Professor C. H. Browning, at the University and the Western Infirmary, Glasgow, with the help of various assistants, carried out, at the request of the Council, a useful investigation into the problem of chronic carriers of enteric infections. It appears that human beings are the sole source of the specific organisms, and that chronic carriers play an important part in the maintenance of enteric diseases. The medical treatment of carriers is, unfortunately, highly unsatisfactory, but surgical measures in cases in which the gall-bladder has been shown to be the reservoir of infection have been successful enough to justify their employment. Another bacteriological problem of importance to the public health that has been the concern of the Council is bovine tuberculosis. Dr. L. Jordan of the Hannah Dairy Research Institute has published a report on a large-scale experiment, promoted by the Council, in the eradication of tuberculosis from herds in an area of nine square miles in Ayrshire. Thirty farms were included in this experiment. The farmers were provided with free tuberculin testing and free expert advice, on the understanding that they would try to eliminate tuberculosis from their herds by isolation methods. Twenty of these farms were free from infection at the end of the experiment, as compared with eight at the beginning, and the results show that eradication of tuberculosis from heavily infected herds is by no means an impossible matter. The Council states in its report:

"It is, nevertheless, important to note that, unless and until absolute eradication be accomplished, efficient pasteurization of milk remains an essential second line of defence in safeguarding human health. . . . Pasteurization, moreover, gives protection against other diseases derived from cattle, preventing the transmission of bovine streptococcal infection and that of undulant fever. It may be added that the Council are not aware of any trustworthy evidence that pasteurization, if properly carried out, has any seriously damaging effect upon the nutritive qualities of the milk."

RESEARCH ON VITAMINS

One of the most significant advances made in vitamin studies is the recent identification of vitamin C as an exact chemical substance. In 1924 Dr. S. S. Zilva, working for the Council at the Lister Institute, discovered that active concentrates of the vitamin had a strong affinity for oxygen. Later, the Hungarian worker Dr. A. Szent-Györgyi observed that the properties of a substance he had isolated from the suprarenal cortex—hexuronic acid—were similar to those Zilva had shown were associated with vitamin C. In 1932 it was shown by Professor Tillmans in Germany that Zilva's "associated principle" and Szent-Györgyi's hexuronic acid were identical with the vitamin itself. This has been confirmed by Szent-Györgyi, and his substance, now known as ascorbic acid, is generally accepted as being pure vitamin C. Dr. S. S. Zilva, working at the Lister Institute, and in conjunction with the staff of the Low Temperature Research Station, Cambridge, has shown that Bramley's seedling apples keep their vitamin C

¹ Report of the Medical Research Council for the Year 1932-3. London: H.M. Stationery Office, 1934. (2s. net.)

² *Lancet*, 1933, ii, 66.

activity at long periods when stored at -20°C .; when stored at higher temperatures the apples progressively lose this activity. It has been shown by other workers that the vitamin C activity of apples is inversely related to their nitrogen content, and it is also related to the number of the nuclear chromosomes of this fruit. Dr. J. Gough and Dr. Zilva have found the anterior lobe of the pituitary gland to be especially rich in ascorbic acid, as is the suprarenal cortex. The view that the suprarenal cortex might synthesize vitamin C is disproved (by work at the Dunn Nutritional Laboratory, Cambridge) by the fact that adrenalectomized rats are still able to form the vitamin. Dr. L. J. Harris and Dr. E. W. Fish have produced experimental evidence that the first effect of vitamin C deficiency on tooth structure is to cause loss of function and degeneration in the formative tissues. In the bones such deficiency results in degeneration of osteoblasts and cessation of formation of new bone.

Mrs. Mellanby's work on dental caries has recently been reviewed in the *Journal*: "The Council regard this work as of much promise for the substantial reduction of the present scourge of dental caries." In last year's report reference was made to the chemical investigations into the structure of the sterols, including calciferol (pure crystalline vitamin D). It was shown that they were

related to such physiologically important substances as the bile acids and sex-hormones; to these may now be added carcinogenic substances isolated from tar. Mr. Webster, investigating the distribution and fate of vitamin D in the body, has found that, in contrast to vitamin A, it is distributed almost uniformly in the fats present in the major organs—with the exception of the brain. Attempts to extract the natural vitamin D from the sterol fraction of cod-liver oil have so far failed, and work has also been done on the origin of vitamin D in the liver of the cod, which is a deep-sea dweller. A small but constant amount of the vitamin has been found in the copepods, which are the principal food supply of this fish in spring and summer.

Dr. Parks (U.S.A.) has assisted at the Dunn Nutritional Laboratory in studies on the way in which vitamin D promotes the assimilation of calcium and phosphate. As opposed to the theory that this vitamin acts by stimulating the parathyroid glands, it was found that the latter have no effect in increasing the absorption of calcium and phosphorus in rickets. Dr. Moore has shown that carotene can be utilized in the body as efficiently as vitamin A itself, but it has not yet been found possible to convert carotene into vitamin A outside the body.

(To be concluded)

Ireland

Irish Medical Dinner in London

On St. Patrick's Day about seventy members and guests of the Irish Medical Schools' and Graduates' Association dined together at Claridge's Hotel. Colonel G. A. Moore, C.M.G., D.S.O., presided over the function, and the principal guests were the Earl and Countess of Iveagh and Lieut.-General J. A. Hartigan, C.B., C.M.G., D.S.O., the new Director-General of the Army Medical Services. During the evening the chairman of council of the association, Mr. W. McKim McCullagh, announced the presentation of the Arnott memorial medal, first awarded in 1900, to the late Mr. E. Canny Ryall. He explained that this was a medal awarded only to Irish medical men who had brought distinction to their profession and their country, either by some act of heroism or by some outstanding medical achievement. Mr. Canny Ryall's claim to the distinction was his foundation of a hospital in London, All Saints', in 1911; last year it moved into more spacious quarters than the other hospitals, St. Peter's and St. Paul's, devoted to the same specialty. Before his death Mr. Ryall learned, and expressed pleasure in the fact, that the association had decided to award him the medal. Mr. McCullagh then handed the medal to the president for presentation to Mr. Ryall's widow, and the company drank a silent toast. Sir William de Courcy Wheeler, in proposing the health of the guests, said that Lady Iveagh had been invited as the guest of honour as a small tribute to her work during the meeting of the British Medical Association in Dublin last July. In spite of some preliminary anxieties, the meeting proved one of the most successful in the hundred years' history of the Association, and "Did more for Ireland in one week than the statesmen had done for seven years." This was due not a little to the fact that Lord and Lady Iveagh threw themselves heart and soul into its hospitalities, even placing their mansion on St. Stephen's Green at the disposal of the ladies' club. As for the other distinguished guest, Lieut.-General Hartigan, who came from Limerick, Irishmen rejoiced in the fact that one of their race again was at the head of the Army Medical Services,

remembering what was done for those services by another great Irishman, Sir Alfred Keogh of Roscommon, before and during the war. In a charming response, Lady Iveagh, M.P., after remarking that she, herself, was only one-quarter Irish, said that all the things she had found best worth having in life had come from Ireland—including her husband. She professed her lifelong interest in hospitals and in medicine, though she realized that an interest in things medical should not lead the lay person to do any amateur diagnosing, and for her own part she knew just enough of medicine to know that she knew nothing at all. For family reasons, she owed a debt of gratitude to the medical profession. Lieut.-General Hartigan proposed the health of the association, whose president, he said, was a very old and esteemed friend and brother officer. As Director of the Army Medical Services he could not forget that the Irish medical schools had always given the Services the most loyal support. The association was founded in 1878 for the dual purpose of maintaining the status of the profession and of promoting social intercourse among those holding Irish medical qualifications. It was more years than he cared to count since he had had any direct connexion with the Irish schools and hospitals. The hospitals, when he knew them, were always in a state of precarious finance, but no doubt their various chancellors of exchequer were now more at ease owing to the success of the newest Irish industry! Colonel Moore, in response to the toast, delighted the company with a genuine piece of Irish oratory, which any attempt to put on paper would only spoil.

Sir William Whitla's Bequests

Sir William Whitla, past President of the British Medical Association, who died at his home in Belfast on December 11th, 1933, left personal estate in Great Britain and Northern Ireland valued at £85,473. His bequests include £10,000 to the Methodist College, Belfast; his house to the governing body of Queen's University, Belfast, with the earnest wish that it may be used as a residence for the vice-chancellor of the university; and £500 to the Medical Institute, Belfast, the income to be used for payment of the ground rent of the premises in College Square. Subject to other bequests Sir William

Whitla left the residue of his property to Queen's University, Belfast, the income to be devoted towards the fund for the erection of a hostel for male students attending the university, or for the erection of a ceremonial or common hall within the university. The Medical Institute building in Belfast, it may be recalled, was erected, equipped, and presented to the Ulster Medical Society by Sir William Whitla thirty-two years ago.

Scotland

Heredity and Health

An address on recent researches into the question of heredity and health was delivered by Professor F. A. E. Crew of Edinburgh University on March 13th in the McLellan Galleries, Glasgow. Professor Crew said that in the past medicine had concerned itself almost entirely with attempts to prevent and control diseases due to environmental causes. For this reason bacteriology had achieved a great development during the last half-century, and it might be assumed that, in the future, prevention of disease due to these causes would become more and more complete. As a result of this, defects and derangements of genetic origin would attain greater importance. For example, diseases of the respiratory system, which were responsible for a greater number of deaths than diseases of any other system, were being prevented, and controlled, so that many persons would in future survive, ultimately succumbing to diseases that occurred much later in life. The increase in the incidence of cancer was partly due to this cause, for cancer was essentially a disease of late middle age. An examination of the causes of death with reference to age showed that diseases of infancy and adolescence were mainly environmental in origin, whereas diseases of middle age and senescence were constitutional and genetic. Therefore, in a population with increasing average age medicine would become more concerned with the problem of preventing and treating constitutional or genetic disorders. From the point of view of society defects of the mind were more important than defects of the body, and one of the greatest problems confronting society to-day was that concerned with mental defect.

Glasgow Hospital for Sick Children

At the annual meeting of the Royal Hospital for Sick Children, Glasgow, the Earl of Home intimated from the chair that £40,000 had been subscribed in response to a special jubilee appeal for funds for the development of orthopaedic work at the hospital. Mr. Robert F. Barclay, chairman of directors, stated that for a considerable time they had been pressed by doctors and health authorities to develop orthopaedic work on modern lines. The Central Council for the Care of Cripples in Great Britain had sent a representative from London to interview them on the matter. The object of orthopaedic treatment was to convert into healthy, capable, and useful men and women children who suffered from such conditions as rickets, infantile paralysis, congenital dislocation of the hip, curvature of the spine, knock-knee, club-foot, and other diseases that entailed disablement and deformity. Under the scheme the hospital would provide accommodation for out-patients as well as wards for in-patients, and there would be operating theatres and special appliances. It was proposed also to make provision for paying patients. Of the sum necessary to enable the hospital authorities to proceed with the scheme

£10,000 was still outstanding. Sir Robert Bruce said that in the hospital and its country branch 7,200 cases had been treated during the past year, while the attendance of out-patients at the hospital and dispensary had reached the figure of 102,466. The hospital was crowded, and there was a long waiting list. The finance of the hospital had been satisfactory, and the general subscriptions had been well maintained. It was remarkable that the sum of £4,094 received from public works showed a diminution of only £87 as compared with that for the previous year. A modern x-ray installation had been provided at a cost of £2,000 by Mr. Robert Barr.

Rowett Research Institute

Dr. R. C. Garry has been appointed to the post of senior physiologist at the Rowett Research Institute near Aberdeen in succession to Dr. H. E. Magee. Dr. Garry graduated M.B., Ch.B. at Glasgow in 1922, when he gained the Brunton Memorial Prize. After a year as resident physician and surgeon in the Western Infirmary, Glasgow, he took up research work at the Institute of Physiology in that city, and in 1924 became assistant to the late Professor Noel Paton. In 1925 he became lecturer and Muirhead demonstrator in experimental pathology, and in 1929 was appointed lecturer in physiology at Glasgow University. In 1933 he gained the degree of D.Sc. for research in physiology. His work in Glasgow was concerned with the physiology of nutrition, especially the functions of the digestive organs. Dr. Garry has published a number of papers on his research work.

Edinburgh Dispensary for Skin Diseases

At the annual meeting of the Edinburgh Dispensary for Skin Diseases Lord Wark referred to the useful work that this institution had done. During the past year 643 patients had been treated, of whom 603 belonged to Edinburgh, the number of attendances being 1,789. The institution had managed to pay its way, but, like other charitable organizations, it must continue to appeal to the public for assistance. Dr. Robert McLaren, honorary medical officer of the Dispensary, pointed out that more than half the cases were those of children under 14.

England and Wales

London Hospitals and Medical Services Committee: Medical Members

In the allocation of members of the new London County Council to the various committees full advantage has been taken of the presence of the many medical men and women on the council in arranging the membership of the Hospitals and Medical Services Committee, which carries on the principal tasks of the former Central Public Health Committee. Of the seventeen members appointed by the council from among its own number seven are medical members—namely, Dr. C. W. Brook, Dr. S. Monekton Copeman, Mr. Somerville Hastings, Dr. S. W. Jeger, Dr. F. Barrie Lambert, Miss E. Rickards, and Dr. Henry Robinson—while among seven non-members of the council a further two medical members have been appointed by the council—namely, Mr. H. L. Eason and Dr. H. Winch—and there remains one vacancy. The Housing and Public Health Committee includes at present only one medical member, Dr. J. A. Gillison, though there are some vacancies to be filled. Dr. S. Monekton Copeman and Dr. Henry Robinson have been appointed.

to the Mental Hospitals Committee, and it is gratifying to note that among the others, not members of the council, whom the council has appointed is Dr. Adeline Roberts, a former member. Mr. Somerville Hastings and Dr. F. Barrie Lambert are members of the new Public Assistance Committee, and Dr. C. W. Brook is to be chairman of the Committee on the Welfare of the Blind. On the other hand, among the thirty-eight members of council and the twelve non-members appointed to the new Education Committee there does not appear to be a single medical man or woman.

Norwich Health Congress

This year's congress of the Royal Institute of Public Health will be held at Norwich from Tuesday, May 15th, to Sunday, May 20th. The scientific proceedings have been arranged in five Sections. The presidential address in the Section of State Medicine and Industrial Hygiene will be delivered by Dr. S. Monckton Copeman, F.R.S., on the scientific investigation of small-pox and vaccination. There will be discussions in this Section on the problems relating to milk and the slums; the first will be opened by Dr. T. Ruddock-West, county medical officer of health for Norfolk, and the latter by Dr. C. Killick Millard, medical officer of health for Leicester. Lady Barrett, president of the Section of Women and Children and the Public Health, will deliver an address on the role of the medical practitioner in the care of mother and child. Three discussions have been arranged in this Section, the subjects being the crippled child, the rural midwife, and the difficult child problem. In the Section of Tuberculosis Dr. S. Vere Pearson will open a discussion on the arrangement of institutions in public tuberculosis schemes. The president of the Section of Pathology and Bacteriology, Dr. G. P. C. Claridge, will give an address on bacterial carriers. Film demonstrations will be given on the destruction of living cells by invisible ultra-violet rays, the present position of diphtheria immunization, and the Holborn diphtheria immunization clinic. In each Section a number of independent papers will be read on various topics, including the control of industrial rheumatism; the sanitation of holiday camps; eugenics and sterilization; noise and the public health; the organized treatment of motor accidents; the problem of the child with otorrhoea; parentcraft; the management of the young delinquent; early diagnosis of tuberculosis in infancy and childhood; vitamins from marine sources; pasteurization as a means of safeguarding the milk supply; the canning of fresh fruit and vegetables in relation to health; dental lesions as the first sign of a disturbance of physiological function; serological observations from cases of cancer under treatment; and great epidemics of the Middle Ages, with special reference to Norwich and Norfolk. The congress is open to any who are interested in public health questions; membership fee one guinea. Further information may be obtained from the Secretary, Royal Institute of Public Health, 23, Queen Square, W.C.1.

The Leeds Workpeoples' Hospital Fund

The forty-seventh annual meeting of this fund was held recently at the Town Hall under the chairmanship of Mr. Harold Collinson, one of the honorary surgeons to the Infirmary. The history of this fund, which has been previously referred to in these columns, is full of interest and of encouragement. The leading spirit in the initiation of the scheme was the late Mr. Fred. Spark, and by him the foundations were well and truly laid. The main source of income is derived from the weekly contributions of the workpeople of the city. This is also the most reliable source, and its steady increase shows the real progress of the fund. At first the weekly subscriptions

came only from the works within the city boundary, but of late there has been an increase in the collecting area, and this has been given expression to in the new title of the fund—namely, "The Leeds and District Workpeoples' Fund." The income for the past year reached the record total of £66,572, of which upwards of £60,000 came from the regular weekly subscriptions from works, shops, and offices. The following grants were made to the various charitable institutions:

	£
General Infirmary at Leeds	35,000
Public Dispensary and Hospital	5,350
Hospital for Women at Leeds	4,350
Leeds Maternity Hospital	2,300
Leeds District Nursing Association	1,450
Children's Convalescent Fund	260
Poor Children's Holiday Camp Association	100
Invalid Children's Aid Society	100

Besides many smaller donations to other institutions.

An indication of the growth of the fund is shown by the amount of the grant to the Infirmary in the two years 1911 and 1933, for in the former it was £5,250 and in the latter it reached £35,000. These figures reflect the greatest credit on the organization, and on the enthusiasm of the many workers whose co-operation has been secured.

Central Midwives Board

At the March meeting of the Central Midwives Board for England and Wales reports were received from the Royal College of Surgeons, the Queen's Institute of District Nursing, and the Society of Medical Officers of Health, that Mr. Victor Bonney, F.R.C.S., Mrs. Elena Richmond, and Dr. J. J. Buchan had been respectively re-elected as representatives on the Board for the year commencing next April. The Standing Committee reported a letter from the medical officer of health for Norwich, stating that his Maternity and Child Welfare Committee had requested the Board "to consider the desirability of framing a more definite rule (Rule E.1) that certified midwives shall regularly examine patients ante-natally and stating the minimum amount of ante-natal work to be demanded from certified midwives." It was agreed to reply that the Board was revising the rules in Section E and that the rules, as revised, would require midwives to see their patients during pregnancy as often as necessary, and also that with the rules, as revised, would be issued a comprehensive leaflet on ante-natal care, a knowledge of the contents of which should make quite clear to midwives their duties in this matter. Approval as lecturer was granted to Dr. Isabella Margaret Currie, York Maternity Hospital, and Dr. Doris Onions, Middlesbrough Municipal Maternity Home. It was reported that a large number of replies had been received to the Board's inquiry as to the attendance of pupil midwives at venereal disease clinics, with the object of obtaining instruction on venereal diseases. In the majority of cases it appeared that either the pupil midwives were attending venereal disease clinics or hospitals at which such cases were taken, or that arrangements for them to do so would be made.

Maternity and Child Welfare Propaganda

The National Baby Week Council offers for annual competition silver challenge shields and other awards for the most novel and effective maternity and child welfare propaganda conducted during the year. In 1933 Northampton secured first place among the great towns for which the "Astor (1931)" shield is reserved. As Northampton won this trophy in 1932, and under the regulations is ineligible to hold it for two years running, it will be held for the present year by Rothwell (Yorks), the next in order of merit. Northampton's success has

been recognized by presentation of a special certificate of merit. The "Kettering" shield, the second award for the large towns, has been won by Sunderland. For areas of population of 15,000 and less the "William Hardy" shield has been awarded to Bungay (Suffolk) for its excellent campaign during 1933, and Buckhurst Hill (Essex) is second in order of merit, thereby winning the "Gwen Geffen" Rose Bowl. Gloucester, Middleton (Lancs), Darlington, Wealdstone, Forton (Gosport), Lane End (Bucks), and East and West Molesey were all highly commended. The awards were presented at the annual meeting of the National Baby Week Council on March 14th.

India

Public Health Commissioner's Report for 1931

In this report, which has been recently received, Major-General J. D. Graham, I.M.S., Public Health Commissioner with the Government of India, insists on India's need of an organization which shall be capable of framing and conducting a public health policy for the country as a whole. Such a Ministry of Health, he adds, is found in Canada, Australia, and South Africa, and is none the less necessary in India because the executive control of public health has been transferred to the Provinces. A census was taken in February, 1931, and the vital statistics for the year can be more accurately estimated than in the nine previous years, the last census having been taken in 1921. The birth rate for the year in British India was 34.3 per mille, as compared with 33.4 on the estimated population for 1930, and 35.7 for the previous quinquennium (based on the 1921 census). The general death rate was 24.8 per mille, and the death rate for infants under the age of 12 months per 1,000 live-births was 178.8, as compared with 180.8 in 1930 and 177.6 in the previous quinquennium. Out of every 190 deaths recorded, forty-three occurred in children below the age of 5, and forty-eight in those below the age of 10. The infantile death rate for British India was nearly 2½ times that for England and Wales and South Africa; more than double that for Germany; and nearly 5½ times that for New Zealand. Countries in which the figures compare more closely with those of British India include Rumania, Hungary, Japan, Italy, Egypt, and Soviet Russia. The three main causes of infantile mortality are given as congenital and developmental defects, alimentary disturbances, and infective disease, the first accounting for nearly all stillbirths and deaths in the first seven days of life, while the two latter affect the older children. Sanitary improvements have operated against the two latter causes, but not against the first, and in the production of these defects prematurity plays an important part, resulting from chronic infections such as syphilis, constitutional weaknesses, acute diseases, accidental causes, and obstetrical emergencies. The conclusion is drawn that, in order to lower the present high infantile mortality rate, the maternity services must be rendered much more skilful. Antimalarial campaigns continued during the year under review, including cinchonization schemes where funds permitted. Tuberculosis is believed to be generally on the increase, especially in some of the larger and more overcrowded cities, such as Peshawar, Delhi, and Calcutta. The anti-tuberculosis campaign has not proceeded very far as yet, but the disease is now notifiable in the Punjab, the Central Provinces, Madras, Baluchistan, and in municipal areas in Assam and the Upper Provinces. In Bombay Presidency, out of every 1,000 deaths recorded in 1931, 43.6 were ascribed to pulmonary tuberculosis; the corresponding figure in 1930

was 39. Recent stimulus to the closer study of this disease in India has been afforded by the programme of the King George Anti-tuberculosis Fund, which is concerned chiefly with the organization of local associations, propaganda, and education. In 1931 there was a huge fall in the incidence of cholera in British India, apart from the Presidency of Bombay, but high mortality curves were present in Bengal and Bombay. The death rate for plague was, however, twice that in 1930, although lower than that in 1929, the Upper Provinces suffering most, as usual. A series of simple leprosy surveys, which had been continued during three and a half years, were ended in 1931. They showed that leprosy was much more prevalent in India than was formerly supposed; probably one million cases would not be an overestimate. The disease was found to be most common among semi-aboriginals or aboriginals, who left their tribal seclusion and hired themselves out to agriculturists or industrial concerns. Infection of the more advanced classes of the community was in the first place largely attributable to the employment of servants in an infectious stage. Once the infection had entered a family it tended to spread in that family, and was often transmitted to friends and acquaintances. It was also concluded from these surveys that leprosy is probably very widespread, but only develops into clinically or bacteriologically recognizable cases in a small fraction of those infected, the natural resistance of the remainder being sufficient to prevent the disease from developing. When leprosy does develop it indicates either hyperinfection or—probably more commonly—lowered resistance. This lowered resistance appears to be due chiefly to various factors affecting the general health, among which are diseases such as syphilis and filariasis, improper diet, and unhealthy habits and surroundings. Movements of the population, which have increased on account of better education and transport in recent years, are a potent factor in spreading the disease and infecting new areas. As this is General Graham's last annual report as Public Health Commissioner, he briefly reviews his decennium in that office, and indicates the more salient advances. He feels that, while an All-India Hygiene Institute should be able to supply highly trained officers for directional work, the backward state of rural hygiene, which is one of the most serious problems in India, can only be approached hopefully by an alliance of medical practitioners with administrators, sociologists, and plain citizens. A commission to take stock of the health position of India might pave the way for some more permanent system of economic advancement. With the coming of a federal constitution, General Graham concludes, a federal health organization worthy of India must soon take shape.

All-India Medical Licentiate's Conference

At the twenty-sixth session of the All-India Medical Licentiate's Conference, held in Bombay last December, Dr. U. B. Narayanrao delivered an address of welcome in which he appealed for more support of their association, suggested some reforms, and pleaded for a greater unity of medical practitioners in India. After emphasizing the importance of post-graduate training in promoting and maintaining clinical efficiency he said that the curriculum of the medical student was cumbersome, and inadequate attention was being paid, therefore, to some of the more important practical sides. A system of polyclinics might succeed as well in the villages as in the towns, and would serve to protect medical work from interference by un-instructed laymen. Dr. Narayanrao deplored the fact that out of about 20,000 Indian medical licentiates only 2,500 were members of their own association. Until that failure to co-operate was overcome, attempts to remedy unsatisfactory conditions must remain feeble.

Reports of Societies

RESULTS OF TREATMENT OF CANCER OF THE UTERUS

At a meeting of the Medical Society of London on March 12th, with Sir JOHN THOMSON-WALKER, president, in the chair, a discussion took place on "The Results of Treatment of Cancer of the Uterus."

Mr. VICTOR BONNEY said that surgical practice in regard to carcinoma of the cervix had been for many years a settled affair, and therefore the results also were constant. Up to the end of 1928 he had performed Wertheim's operation for this condition 366 times, and the five-year cure rate was 40 per cent. if the patients who had been lost sight of and had died of other diseases before five years were included, or 41 per cent. if they were not. Up to the end of 1923 he had performed this operation 266 times, with a ten-year cure rate of 30 or 34 per cent., according to whether the patients who had been lost sight of or had died of other diseases before ten years were included or not. Ten years' freedom from recurrence could be claimed as an absolute cure. His operability rate was reckoned as 63 per cent. The results of surgery in carcinoma of the cervix were best expressed by saying that it succeeded in keeping cancer-free for five years two out of every five patients operated on, and one out of every four patients seen; and in absolutely curing—taking as the basis of cure a ten-year freedom from recurrence—one out of every three patients operated on and one out of every five patients seen. These results had now been constant for many years. He gave figures showing how much better the prognosis was in the cases in which the regional glands removed at the operation were found to be free from growth. His five-year cure rate for "gland-free" cases was over 50 per cent., while for "gland-invaded" cases it was only 21 per cent. His operative mortality for the last 200 cases he had treated was 10 per cent.

In any discussion on the relative values of operation and radiation, Mr. Bonney continued, the real comparison was not between the results of operative treatment and the results of radiation treatment, but between the results obtained, on the one hand, by operating on a proportion of the cases and radiating the remainder, and, on the other hand, by radiating all cases. Of the patients on whom a surgeon could not operate a certain number could be salvaged by radium, and the number of these had to be added to the number of operative cures in assessing the total achievement. A surgeon operating on a proportion of his patients and radiating the remainder should obtain from thirty to thirty-one five-year cures out of every hundred unselected patients who presented themselves. A direct comparison between operation and radiation founded on the surgeon's operability rate and the number of so-called "operable cases" (Class I and II) treated by the radiologist was useless. A better way was to contrast the results obtained from similar percentages of the total number of patients seen, though even this method had its inaccuracies. The difficulty of comparing surgery and radium might be likened to an attempt to assess the relative values in war of high-velocity guns and trench mortars respectively; they were weapons with different ranges. The truth of the matter probably was that, if only there were sufficient understanding, cases of carcinoma of the cervix would be divided into four classes—namely, those in which a cure could be effected (1) only by operation; (2) only by radium; (3) either by operation or by radium; and (4) those in which a cure was impossible by either method. When a way was discovered whereby invaded glands and cellular tissue on the wall of the pelvis could be cured by radiation, radiation treatment applied to all patients would give better results than to operate on a proportion of them and apply radiation to the remainder.

THE CASE FOR RADIOTHERAPY

Dr. MALCOLM DONALDSON said that he disagreed entirely with Mr. Bonney. He first took up Mr. Bonney's

point regarding an operability rate of 63 per cent. The average number of cases operated on by Mr. Bonney in hospital worked out at seventeen per year; therefore Mr. Bonney, notwithstanding his fame for this operation—a fame justly earned—only saw twenty-seven cases a year. This number surprised the speaker when contrasted with the much larger number seen at institutions where radiation treatment was applied. The report of the Ministry of Health on cancer of the uterus declared that the operability rate varied in different districts, and from year to year in the same district according to the practice and judgement of the individual surgeons and the nature of the treatment employed. In discussing the results of radium therapy, he said that unfortunately in England there were not at present any mass statistics as to the five-year survival rate, but in a few years' time he thought figures would be available which would startle even Mr. Bonney. The best statistics were those from the Madame Curie Hospital at Hampstead, where, during the period 1926-32, 171 patients had been treated, of whom 141 were alive at the end of 1932. In institutions devoted to radiotherapy the cases were divided into four stages, according to the extent of the growth, and these figures appertained to the first two of these stages, the first being one in which the growth was strictly limited to the cervix, and the uterus was mobile; and the second, one in which there was some spreading of the lesion, though there was still a certain amount of mobility of the uterus. At University College Hospital between 1921 and 1931 the number of cases of the disease in these two stages treated was 101, and forty-eight patients were alive at the end of 1931. At Mount Vernon Hospital, which only started in 1930, fifty-eight patients had been treated, and thirty-nine were alive at the end of 1933. He fully realized that these statistics were too small and recent to be of real value in making a comparison, but they gave promise for the future. In addition to these there were a number of "inoperables" alive, though it was difficult to talk in percentages, because one institution would send away cases which obviously could not be cured, although they might be made more comfortable, while another would treat practically every case.

Dr. Donaldson added that when he started radium therapy at St. Bartholomew's the technique was one in which the needles were inserted all round the cervix, but about 1929 he realized that this technique was not the best, and he gave it up. Actually at St. Bartholomew's there were 113 patients classified as belonging to the first two of the four stages, and forty-one were alive in 1933. There were, of course, other points to consider besides statistics. The fear of a big operation deterred a number of people from seeking advice, and that fear would disappear to a large extent on the adoption of radiotherapy. Again, it required a surgeon of exceptional skill and experience to do a first-hand hysterectomy, but once the best technique for radiotherapy was worked out people could be trained by the hundred to follow it. Mr. Bonney had stated that one of the great disadvantages of radiotherapy was in the treatment of glandular invasion, and that radium in the vagina could not deal with carcinoma in the internal iliac glands. On looking at Mr. Bonney's figures, however, it appeared that in 57 per cent. there were no glandular metastases, and of these 10 per cent. died as a result of the operation. Surely it was fair to suggest that most of these cases might have been cured by radiotherapy. Mr. Bonney had not mentioned that every radiological institute was now treating the glands by means of x rays, and one could not help believing from the figures—figures from foreign sources, he admitted—that there must be some value in such treatment. It was the Stockholm technique, with some modifications, which was chiefly used in this country. It consisted of placing radium into the cervix and body of the uterus (roughly 40 to 50 mg.) and into the vagina (60 to 70 mg.). This was done on three occasions, and the original Stockholm technique was twenty-two hours on each occasion, with an interval of one week between the first and second application, and of three weeks between the second and third. He had modified that at Mount Vernon, where a week's interval was given between the

first and second, and a week's interval also between the second and third. The same filter was used—namely, 1.5-mm. platinum—and a further modification was to have a special pessary for holding the radium rather than simply packing it by means of gauze. On this question of treatment he added that it was not only a matter of getting radiation to the glands. There were many parts of the body where it was quite easy to get a very big intensity of radiation to the glands, but even then it was found difficult to "knock out" the carcinoma cells. There were two possible explanations: one that the glands actually encouraged the growth, and the other that the glands, being radio-sensitive in themselves, were "knocked out" before the carcinoma cell. As for carcinoma of the body of the uterus, he believed the right treatment was surgery, followed by deep x-ray therapy.

THE PERSONAL FACTOR

Mr. V. B. GREEN-ARMYTAGE began by paying a tribute to Mr. Bonney for his skill in this operation; he had "out-Wertheimed" Wertheim. The question that worried him was as to the likelihood of any of the younger generation of surgeons acquiring anything like Mr. Bonney's degree of experience and dexterity. The number of cases which went to a London hospital per annum was very small, so that the younger surgeon was not likely to see many of these cases, and would be denied the opportunity of achieving the completeness in technique that Mr. Bonney had exemplified. That being so, was it not rather dangerous for a surgeon to try to copy Mr. Bonney? Surely his results were likely to be very poor, and the chances of recurrence considerable? The speaker asked what would be the reaction of any of those present in a case in which a member of their own family was concerned when the alternative was a Wertheim operation, not done by a master like Mr. Bonney, but by a general surgeon, an operation having an immediate mortality of 15 per cent., and a cure rate of 40 per cent., and involving months of invalidism and pain, as contrasted with radium treatment, which had practically no immediate mortality, no pain, and in which the end-result showed about the same cure rate. He believed that radium or x rays at 800 kilovolts was likely to displace operation. After having visited Vienna on several occasions, he was astounded on going there in 1931 to find that "the shadow of the wings of Wertheim had practically disappeared from the wards of the Vienna clinics." There were practically no Wertheim operations being done in the large hospitals of Vienna, where radium therapy had displaced operation.

Mr. STANFORD CADE said that it was logical to assume that if a case which was advanced and was not suitable for operation still yielded some small percentage of success, even to complete disappearance for five years, to radium treatment, radium would be proportionately efficacious in a much larger number of early cases. With regard to the lymphatic glands, the medical profession had become quite convinced that glands which were the seat of secondary deposits were very radio-resistant. He himself had treated a very large number of necks with malignant deposits in the cervical glands, and it was his experience that it was quite possible, by means of radiation, to cause shrinkage of glands with secondary deposits, and for the patient to remain free from recurrence for many years. He had in mind one case which had been free for eleven years. The lay person could not possibly compare treatment by means of a Wertheim operation, which in the hands of an average surgeon—not Mr. Bonney—presented a grave risk to life, with treatment by radium, which should present no immediate risk to life. The position must be borne in mind of patients who, although affected by carcinoma of the cervix, would like to live for a few years longer, and not to pass out through the portals of surgery. There were, of course, certain dangers in radiation, especially burns, which came on insidiously, manifesting themselves months after the treatment. But he felt convinced that by a combination of x rays and gamma radiation a much wider number of patients could be reached, and by such a combined method a greatly increased dose, up to 50 per cent., could be

delivered than by either of these weapons alone. In the future there would be no such thing as radium treatment and x-ray treatment of carcinoma of the cervix, but a combined treatment, and by a combination of the two methods a very much higher intensity could be achieved and better results might be anticipated.

Dr. J. E. A. LYNHAM said that when he was in Stockholm about six years ago a kind of review of a very large number of patients with carcinoma of the cervix treated by radiation methods was presented, and he was deeply impressed by the courage of the clinicians, who put forward not only the groups of patients who had been cured, but the much larger groups of whom it could not be said that the disease had been eradicated, though they were leading useful and comfortable lives. These people had been treated either by radium or by radium and x rays both. In all these varieties of treatment there was a very great personal factor. Operation in the hands of one surgeon was a phenomenal success and in another was a failure, and the same was true of radium and x rays and every form of therapy. He himself began in the early days of the Radium Institute in London in 1911, when nothing was known about the possibilities, although tremendous hopes were entertained. The cases sent to the Institute were the disasters of the medical profession, cases in which there was no possibility of any sort of cure. But among these, as a result of careful and painstaking treatment, there were a number who were restored to an ordinary social existence, relieved from pain, haemorrhage, and discharge, and made to lead useful lives for many years. Among them were a few absolute cures. He could quote a small number living to-day who were regarded as far back as 1913 as surgically inoperable. He passed in review the successive techniques which were employed. It was early realized that while results could be obtained within a short range of the radium applicators, the disease in a great many cases spread beyond the limits of their treatment. In his personal experience these cases fell into fairly definite groups. There was the group where the disease was essentially local, and he did not think that up to date there was anything to offer in opposition to the claims of surgery in the treatment of such cases. Then there were cases which were just beyond the range of local operation, where the broad ligament was involved, or the glands could be felt, or the disease had spread to the pelvic wall. Here he thought radium, as well as surgery, was of service. Again, there were cases which had ascended beyond that range, where the glands extending up into the abdomen were involved, and for such cases he did not think either surgery or radium would be successful; he believed that they should first have a radium treatment, based more or less on the Stockholm technique, and subsequently be given x rays with a view to irradiating the glands of the abdomen. One had to try to visualize the pathological process at work, and to direct the radiation so as to give doses which might help the natural conservative forces of the body—surgery first, radium next, then perhaps the two combined, and, for cases which had gone beyond those limits, the x rays also.

Mr. ARNOLD WALKER said that after some experience of using the Stockholm technique he thought that for operable growths results could be achieved comparable with those of surgery, and a certain number of "hopeless" cases were saved. But when it came to the borderline type of growth, the Class II and III cases, one was up against the appalling problem of the lymphatic glands, and although it was rare to see a local recurrence, the frequency with which the masses were found attached to the side wall of the pelvis was very distressing. In the London County Council radium centre they were now starting to combine radium treatment with x rays.

OPERABILITY RATES

Mr. VICTOR BONNEY, replying on the discussion, said that so far as his experience went he had never known a recurrence after ten years. He would not say that it could not occur, but it occurred so rarely that if a person lived for ten years the case could be regarded as a cure;

that was not so with carcinoma in other situations—as, for example, in the breast. The operability rate was a very vexed question. In the old days the cases with carcinoma of the cervix at a general hospital would be an unselected series; nowadays, when an institution became associated with the treatment of carcinoma of the cervix, there was a tendency for cases to be sent there, and that disturbed the balance, so that it did not follow that the figures from, say, Mount Vernon, were representative of cases at large. He gave reasons for stating that his own operability rate was 63 per cent. In one group of cases—namely, those whom he saw in his own private consulting room—he could be still more precise. He had operated on 78 per cent. of all these cases which he had seen in his consulting room between the years, he thought, 1910 and 1929, and these were selected cases in the sense that they had been sent to him by practitioners in the hope that by his own method of treatment he could do something for them. In about 40 per cent. of these cases there was glandular involvement. While the operability rate to the surgeon was a well-ascertained figure, he could not say the same of the radiological operability rate; he maintained that there was no relation between the two at all. The radiologist's operability rate was founded on an opinion which varied immensely with the person giving it as to the class to which the case belonged. He was, of course, absolutely convinced that good radium was better than bad surgery, but it should be recognized that surgery had never had the advantages that radium had had in the shape of a national organized effort. Such effort as had been made was by individuals working independently and unassisted. He was not in the least antagonistic to radium; on the contrary, he had tried to hold the balance as evenly as possible. It was in the "gland-involved" cases that surgery came into its own and passed radium, but once radium could deal with the glands he agreed that surgery would be out of it without any doubt at all.

Dr. MALCOLM DONALDSON, also in reply, said that the operability rate was next to impossible to get, and even when it was arrived at there was no use for it except to illustrate how very few cases came forward for treatment at an early stage. Mr. Cade had mentioned the danger of radium burn. At the Madame Curie Hospital an investigation had taken place on this point, and he thought that 7 per cent. of the cases showed some reaction on the rectum in treating carcinoma of the cervix. The other danger in late cases was that of sepsis; it did not arise in the early cases.

ANOREXIA

At a meeting of the Manchester Medical Society held on February 7th, with the president, Dr. C. PAGET LAPAGE, in the chair, Dr. J. A. RYLE read a paper on "Anorexia."

Dr. Ryle prefaced his remarks with a brief consideration of the importance of subjective phenomena in disease, quoting Dr. John Brown, who had said: "Symptoms are universally available; they are the voice of nature; signs, by which I mean more artificial or refined scrutiny, . . . are not always within the power of every man, and with all their help are additions, not substitutes." It was not enough, said the speaker, to be familiar with the names of symptoms and their chief associations; we should seek to appreciate their intimate physiology. Anorexia was a negative symptom, a withdrawal of the normal or healthy function of appetite. The value of appetite as an index of health, and of loss of appetite in its varying degrees as an index of disease, could scarcely be overstressed. Clinical observation had, perhaps, provided more information concerning the appetite sense than experimental physiology. Appetite was different from hunger, which had been exhaustively analysed by physiological experiment, especially at the hands of Carlson. After discussing the differences between these two sensations he suggested as a definition of appetite that it should be regarded as "in part a memory process and in part a local manifestation of efficient and anticipatory alimentary tonus induced by the memory stimulus,

or by the more direct stimulus of seeing, smelling, or tasting food, or by some combination of these several factors." The commoner clinical causes of anorexia were next reviewed, and special attention was drawn to the very complete anorexia which often proclaimed a diffuse carcinoma of the stomach—a condition in which tonic adaptability of the gastric musculature was destroyed. The influence of general infection, and the local effects of gastritis and of psychological factors, were in turn considered. There was no good evidence that the appetite sense was directly related to the secretory activities of the stomach. Special attention was drawn to the lessons which could be learned from cases of anorexia nervosa, illustrative examples of which were furnished. In a series of thirty-eight cases which had come to the lecturer's notice, thirty-five were women, most of them young. Approximately one-quarter of these cases had developed subsequently to a physical illness or operation. Two-thirds of the cases were psychoneurotic, and in some of these "slimming" had initiated the illness. The remaining cases were psychotic. The rational therapeutics of anorexia were finally discussed. In connexion with the frequent association of nervous dyspepsia and poor appetite, fussy and unnecessarily strict dietaries, for which medical men were sometimes responsible, were condemned. Poor appetite in childhood was frequently an expression of negativism, and a healthy appetite reflex could then be reconditioned by a better understanding and sensible handling on the part of the parents. Medical aids to appetite were of a subsidiary value only, and their action was probably by suggestion and not direct physical action.

SWEDISH APPROACH TO DIABETES

At a meeting of the Medical Women's Federation, held on February 20th, with Professor M. F. LUCAS KEENE in the chair, Dr. ANDREA ANDREEN-SVEDBERG opened a discussion on the Swedish approach to the problem of diabetes.

She said that the first thing she did with her diabetic patients was to tell them that they were not ill, but that theirs was a condition which developed into illness if they failed to follow certain rules. One result of telling them this was to make them realize that they were meant to be useful members of society, and could be educated, could work, and earn a living just about as well as anybody. Dr. Svedberg had begun to use the clinical laboratory of the Board of Health of Stockholm as an out-patient clinic for diabetics, she said, in order that the patients should not have to spend hours in waiting at mixed clinics, with the loss of wages and perhaps employment. The clinic was opened in 1925, and in 1927 all the patients attending, with the exception of a few very old ones, were at work. Now, of course, few of the males were in work except boys under the age of 18, who received lower wages. Most of the women were employed, but as a group these patients were hard hit by unemployment, because they were not first-class material. Diabetic children should be allowed to take part in sports and gymnastics. Although they were not ill, diabetic patients must be reminded of certain weak points. They were liable to become infected early, and often severely, and infections tended to make the diabetic condition worse. The beginning of diabetes could not generally be traced, but sometimes it clearly started in connexion with an acute infection, and was associated with pains of pancreatic origin. It was well to insist that a diabetic patient should go to bed for a couple of days when he had a cold. A diabetic patient attacked by a severe infection like pneumonia was seriously handicapped; it was necessary, therefore, to prevent infections as far as possible. The importance of cleanliness had to be emphasized; special care should be taken of all small wounds and abrasions, particularly of the feet, and affected teeth should be attended to. Cases of diabetes were rarely discovered at the clinic; usually the patient or his friends became suspicious of his increased thirst or of other symptoms. A number of milder cases associated with pruritus and eczema occurred in middle-aged women, and were detected by the skin specialist. If the urine

of a patient contained sugar but no ketone bodies, Dr. Svedberg told him to return the next morning, fasting, and with a sample of urine collected over twenty-four hours, for fuller investigation. She generally started mild cases with a fast-day. This often worked miracles in cases with itching eczema and a high blood sugar. The patient spent the day in bed, and drank as much water, tea, or coffee as he wished, and a little broth. She did not use this method in severe cases, or for children or young patients, who would easily get acidosis. Severe cases should not receive ambulatory treatment at the beginning. In treating cases of intermediate severity it was often possible to arrange for a nurse to visit the patient and give the insulin injections until he had mastered the technique. Some observers considered that the blood sugar fluctuated according to a "liver rhythm," rising in the morning and falling in the afternoon. They thought that insulin should be given in accordance with this rhythm, which must be determined for each patient. The evidence had not withstood close criticism, and the most that could be said was that the blood sugar of mild diabetics and normal people fell during the night and the blood sugar of severe diabetics rose, owing to the prolonged fast. It was therefore advisable for severe diabetics to take their morning insulin as early as possible, an hour or two before they took any food. Otherwise insulin could be given just before a meal.

DETAILS OF TREATMENT

In arranging the diet the aim was to keep the urine sugar-free, because sugar secretion meant that the hormonal capacity of the patient was strained to its limit. But a secretion of 0.5 to 0.7 per cent. in the twenty-four-hour specimen could scarcely be avoided in severe cases. She told patients to use the Benedict test, and if there was a change of colour to pea-green, but no further, she considered that the amount of sugar present was sufficiently small to be ignored. Before the diet was laid down the patient was weighed and measured to find out whether his weight was appropriate to his height. A patient weighing 60 kilos and doing light work needed about 1,800 calories a day. As a rule, it was wise to undernourish diabetics a little, because their weight tended to rise under treatment. Dr. Svedberg considered that the standard diet for a healthy man of 3,700 calories a day, recently discussed in England, was unnecessarily high, except in a few cases of extremely heavy work. The upper limit of the intake of carbohydrates was governed by the patient's ability to use them; the lower limit by his needs, by the antiketogenic/ketogenic ratio of carbohydrates to fats, and by the stimulating effect of carbohydrates on the insulin mechanism. It was generally agreed that the dosage of insulin should be kept down as much as possible—large amounts of carbohydrate and insulin meant dangerous fluctuations in the blood sugar. The carbohydrate in a diabetic diet did not usually exceed 100 grams. The protein intake was generally about 1 gram per kilo of body weight, and the upper limit was set by the facts that fully half the amount of protein taken meant sugar in the body, that the amino-acids were to some extent ketogenic, and that carbohydrates were utilized better when the diet was low in protein. Restriction of carbohydrates and protein meant that about two-thirds of the diabetic diet consisted of fat. In 1909 the practice was to give diabetics a diet consisting largely of protein; later, just before the discovery of insulin, the diet was mostly fat. Nowadays we were giving a combination which approximated more closely to an ordinary diet, with a reasonable proportion of carbohydrate. Obese patients with mild diabetes did not readily develop ketosis, and could be given relatively more protein and less carbohydrate and fat. They could take about 1.5 grams of protein per kilo of body weight. Intelligent patients could be told how much carbohydrate, fat, and protein they were supposed to take in a day, and might be left to compose their own menus with the help of a food-table. It should be made clear that nothing was forbidden, provided they kept within the daily amount allowed of each of the three constituents. They should be warned that it was better to make

liberal use of the vegetables with a low carbohydrate content, and to use bread and potatoes sparingly. Less intelligent patients preferred to have a diet planned out for them. The aim was to keep the urine sugar-free in such a way that the patient enjoyed life and used as little insulin as possible. Joslin in America was particularly successful in keeping down the insulin dosage, and claimed that out of 2,000 patients under his care only ten had 60 units daily. This was probably because he was able to persuade his patients to take no bread. A diabetic did well if he was intelligent, methodical, and firm, or if, lacking these qualities, he worshipped his physician. The intelligent ones could shift for themselves, but most diabetics needed control, and should be seen every two or three months, or oftener. Professor Haldane had said that insulin had "saved a few intelligent people, that is all," but Dr. Svedberg considered this view to be too pessimistic. Poverty was a hindrance to insulin treatment. In Denmark the insurance scheme found the cost of insulin for all who could not afford it. In Sweden the larger cities provided the cost when necessary, and in twenty out of twenty-five provinces the cost was met by the central administrative committee; in the other five the old age pension was given in advance to cover the cost of insulin. Statistics on diabetes were so far unsatisfactory, but the diabetic mortality rate had fallen since the discovery of insulin, and diabetic patients now died at a later age.

Dr. CICELY PEAKE recalled Joslin's dictum that diabetic children should be given a small dose of insulin at night, and wondered whether he still held to it. Dr. S. R. EASTWOOD said she had obtained better results with obese patients, she thought, by cutting down the fat in the diet and giving extra carbohydrate. The patient's sense of well-being seemed to be increased. Dr. SVEDBERG replied that she had not tried this plan with obese patients, but that she would do so. She agreed that a larger proportion of carbohydrate made the diet pleasanter to take, but found it difficult to see why the change should benefit the patient otherwise. Dr. G. H. WAUCHOPE remarked on the sensible change which had occurred in the diet of diabetics during recent years. Why should not their diet approximate as nearly as possible the diet of the normal person? It was probably better, she thought, for a patient to pass a little sugar once or twice in the day than to be kept on the verge of hypoglycaemia. She asked whether Dr. Svedberg found that her patients ever developed hypoglycaemic symptoms. Dr. SVEDBERG replied that she had never used diets with a very high proportion of carbohydrates. She seldom saw a case of hypoglycaemia.

NERVOUS COMPLICATIONS OF THE ACUTE FEVERS

At a joint meeting of the Section of Neurology and the Section for the Study of Disease in Children, held at the Royal Society of Medicine on March 15th to discuss the nervous complications of the acute fevers and exanthemata, Dr. S. A. KINNIER WILSON, who took the chair, said that this subject was "one of the growing points of neurology."

Dr. J. D. ROLLESTON read an opening paper, mainly clinical in character, based on observations in the London fever hospitals, and dealing mainly with diphtheria. He said that estimates of the frequency of diphtheritic paralysis varied, but among 2,300 cases of diphtheria which he had seen 20 per cent. developed some form of paralysis. Much lower estimates made by others were probably due to mild forms having escaped attention. Paralysis and loss of impairment of reflexes were more frequent in children than in adults. For the majority of diphtheritic palsies the term "paresis" was more appropriate than "paralysis." The frequency and severity of diphtheritic paralysis bore a direct relation to the character of the initial angina. Paralysis was rare after purely nasal, laryngeal, or cutaneous diphtheria, and after relapses. Before the time of antitoxin early treatment could not cut short the disease or prevent or modify the paralysis,

whereas early injection of antitoxin jugulated the disease and diminished the frequency and severity of subsequent paralysis. No account of diphtheritic paralysis was complete without mention of the rare condition of diphtheritic hemiplegia, which differed from ordinary diphtheritic paralysis in being primarily a vascular lesion—namely, cerebral embolism due to cardiac thrombosis caused by mural endocarditis. Several cases had been reported of recent years, but diphtheritic hemiplegia was a very unusual event. Prognosis as regards survival was good; but unfavourable as regards complete recovery of function. With regard to reflexes in diphtheritic paralysis, Dr. Rolleston said that knee-jerks were more frequently affected than ankle-jerks. Superficial reflexes were only lost in severe cases of generalized paralysis, and such loss was usually of short duration. Babinski's sign was occasionally present in the acute stage of diphtheria. Complete recovery in diphtheritic paralysis was the rule and death the exception. The existence of chronic diphtheritic paralysis was doubtful; he was inclined to think that the chronicity in such cases depended upon some other cause than the diphtheria. The prognosis depended on the age of the patient, the situation of the paralysis, and the date of onset. Prophylaxis by early injection of antitoxin, and rest in bed for periods varying with the severity of the initial attack, was more effective than curative treatment. The treatment of paralysis by antitoxin was of doubtful value; it was strongly recommended by French clinicians, but the success of the method was due less to a specific action than to psychotherapy. Summarizing the principal nervous complications of other acute exanthemata, Dr. Rolleston said that those of scarlet fever consisted of serous meningitis, suppurative meningitis (usually secondary to otitis media), cerebral or cerebellar abscess, and hemiplegia. In measles, although a great deal of attention had been given to encephalitis, nervous complications of any kind were, in his experience, extremely rare. They were rare also in rubella (none had come under his notice, but examples had been recorded), and in varicella and small-pox. Nervous affections were also rare in enteric fever, and some at least of the cases of peripheral neuritis in typhoid fever were really examples of alcoholic neuritis—of therapeutic origin!

Dr. W. G. WYLLIE classified the four commonest varieties of nervous complications following acute fevers and exanthemata as: (1) symptoms suggestive of multiple focal lesions, involving the cortex, basal ganglia, cerebellum, and spinal cord; (2) a myelitic type; (3) a hemiplegic or single focal type; and (4) an ataxic type, sometimes associated with tremor or choreiform movements. The first two varieties were the usual forms of complications following small-pox, vaccination, and measles. Measles, however, was more protean in its nervous complications, and might be followed by any of the four varieties. The morbid anatomy in the majority of cases following these three fevers showed a striking similarity. The same clinical and pathological features were further presented by the cases of acute disseminated encephalomyelitis of spontaneous onset. Clinically and pathologically there was evidence to suggest that the complications of chicken-pox and German measles might also be included in this group. The hemiplegic or single focal type of nervous complication was commonest following scarlet fever and whooping-cough. In either case, up to recently, the importance attached to haemorrhagic lesions, embolic or thrombotic, had been grossly exaggerated. Recent histology much more often pointed to toxic-degenerative changes affecting either the capillaries or the parenchyma. The fourth, the ataxic variety, had been recorded as following several of the fevers—measles, chicken-pox, scarlet fever, diphtheria—and had its counterpart in the spontaneous cases of acute ataxy in young children. The nervous complications of mumps—meningo-encephalitis—were best considered separately. There was apparently a direct connexion between the virus of mumps and the nervous complications. He hoped that some other speaker would deal with the psychotic side, which was not uncommon after acute fevers.

Dr. J. G. GREENFIELD confined his remarks to the pathological aspect of only a few of the nervous complications. He pointed out that in some cases two or more of the pathological conditions occurred together. In measles, for example, acute perivascular myelinoclasia ("acute encephalomyelitis") might occur in association with other nervous complications. The subject was no more simple from the pathological point of view than it was from the clinical. Acute disseminated encephalomyelitis, sometimes complicated by toxic degeneration of nerve cells or haemorrhagic encephalitis, had been shown to follow variola, measles, chicken-pox, rubella, and influenza. In such cases the pathological changes could not be distinguished from those of post-vaccinal encephalitis. Whooping-cough, the nervous manifestations of which had been known and studied for many years, and mumps produced their own types of meningitis or meningo-encephalitis. There was evidence that in mumps an attack of meningo-encephalitis might replace the typical parotitis. Typhus fever also affected the brain with its specific lesions. Toxic changes in nerve cells were specially common in scarlatina and other streptococcal infections, and were also sometimes found in measles. The affected nerve cells might die and disappear. Meningism was a clinical term, and its pathological basis might vary; it might be due to a sudden lowering of the blood chlorides or to anaphylactic oedema of the nervous tissues. Anaphylaxis was a comparatively rare cause of meningism, but well-authenticated cases were on record. Finally, he touched on sinus thrombosis leading to death of cortical nerve cells or to a temporary increase of intracranial pressure; cerebral embolism might also follow acute febrile conditions. Spasm of the small cortical arteries had been suggested as an explanation for the eclampsia of whooping-cough, without positive evidence.

Dr. W. GUNN said that the occurrence of encephalomyelitis in the course of infectious diseases was of extreme rarity, and the cases that had occurred had possibly received a prominence and attracted an attention which was more than they deserved, to the neglect of other neurological complications of the disease, some of which were more amenable to treatment. There seemed to be a definite relation between the severity of the original disease and the subsequent attack of encephalomyelitis, though an exception to this was found in small-pox, where nearly all the cases of encephalomyelitis occurred after the very mild variety. He had had a small series of cases of whooping-cough which went to necropsy. These cases showed the clinical manifestations, from convulsions to coma, of acute disseminated encephalomyelitis, but on an examination of the brain the characteristic changes were found in none of the cases. The changes were simply vascular, congestion, and certain toxic changes which might be secondary to the vascular changes. In none of these cases was the morbid process found which was associated with acute disseminated encephalomyelitis. The question of the aetiology of these diseases was more than an academic one, because it had a direct bearing on treatment. If the hypothesis was true that these encephalitic occurrences were due to the virus of the primary disease, which had a neurotropic property, it postulated that there must be some variation in the soil as well as in the seed, because, in conditions following vaccination, for instance, there was no succession of cases from the same batch of lymph. The more commonly accepted explanation was of a specific virus causing all forms of encephalomyelitis, the infectious disease merely activating this virus, or at least lowering the individual resistance to the virus, enabling it to attack the brain and meninges. If it was true that the virus of measles or variola could attack the brain then a valuable therapeutic effect might be expected from an immune serum for measles or for variola. If a specific virus was responsible, then no therapeutic effect was to be expected from the use of immune serums in general, but only from a serum obtained from a recovered or convalescent case of encephalitis, and whether the case of encephalitis followed measles, rubella, or mumps, as the case might be, that serum should be equally efficacious. Unfortunately, the number of cases reported so far was too few to warrant any conclusion as to the

value of immune serums. The onset of encephalomyelitis was usually so sudden, its evolution so swift, either in the direction of rapid death or complete recovery without any treatment, that it was doubtful whether in such treatment immune serum would ever find a place.

Dr. L. J. M. LAURENT said that there could be no doubt that the severity and frequency of diphtheritic paralysis bore a relation to the severity of the initial toxin, and in cases of comparatively mild attacks of diphtheria where paralysis had followed it had been his invariable experience that either the antitoxin was given too late or was given in inadequate doses. Diphtheritic hemiplegia was a very rare condition; he happened to see two cases twelve years ago, and he had not seen another case since. Both cases recovered, but some spastic paralysis remained. He had never seen in diphtheria a loss of pupillary reflex to accommodation; the paralysis seemed to be one entirely of the ciliary muscle. There was no doubt that encephalomyelitis was a very serious complication indeed, but from the point of view of those who had to treat infectious fevers every day this complication played a very small part. The number of cases showing such complications must be very small. On the question of whooping-cough, he desired to point out that the convulsions were often due to tuberculous meningitis. This condition, as well as generalized tuberculosis, occurred after whooping-cough more often than after any other infectious fever, not excepting measles, and time after time he had seen in the cerebro-spinal fluid tubercle bacilli, proving tuberculous meningitis, when this had not been previously suspected. It was a remarkable fact that the onset of the convulsions of whooping-cough coincided frequently with the onset of bronchial pneumonia, with increase of consolidation in the lung, and many of these convulsive attacks diminished in frequency or severity as a result of prompt administration of oxygen. He hoped that one day there would be a specific antitoxin as a means of treating whooping-cough.

Dr. W. RUSSELL BRAIN said that he found difficulty in accepting what he might call the unitarian theory or the opposite theory. Although these disorders seemed to have a common pathological basis, there were certain distinctive features about them. Dr. Wyllie had mentioned the differences in the mortality and recovery rates, and others might be mentioned—for example, in small-pox, the tendency for curious speech disturbances to develop, and, in chicken-pox, the high percentage of patients with acute cerebellar ataxy, and the very low mortality rate. If all these disorders were due to a common factor, then such factor must be modified or directed in a surprising way against different parts of the nervous system by the predisposing cause. On the other hand, if the primary virus was responsible for these complications, then that exhibited a curious and unexpected selectivity in its effects and in its mortality rate and the incidence of sequelae. Therefore both hypotheses carried with them their own difficulties. A point of some interest was certain recent experimental work on louping-ill, a disease of sheep; it had been discovered that if sheep were infected with the virus of louping-ill alone they developed a generalized illness, but not nervous symptoms, and in order that the nervous symptoms might develop it appeared to be necessary for them to be infected simultaneously with another disease, called tick-borne fever. If that work was confirmed it was of importance, because it was the first example on record of a virus being rendered neurotropic by coincident infection with another virus. It seemed to him quite plausible, *a priori*, that if nervous complications were due to the primary disease, they should be expected to respond to specific serotherapy, but if due to a secondary virus directed against the nervous system by the primary one, on relieving the primary condition by serotherapy the other condition might be expected to subside. He had recently seen a chicken-pox encephalitis in a man aged about 30, who developed his symptoms on the fourteenth day after infection, and went through all the phases, including acute-mental confusion, with bilateral weakness of one leg. He made a good recovery and returned to work, but the plantar reflex was still extensor after three or four weeks.

Dr. J. P. MARTIN said that he had been very much struck by the mental changes in these patients. The physical signs were often relatively slight. They began at first with severe physical manifestations, but when the child had passed the stage of convulsions and came to the stage of coma there might be very little in the way of abnormal physical signs. When the child began to move its limbs the tendon-jerks were perhaps rather depressed and the plantar reflex in a number of cases quite indefinite. There might be signs which were less difficult to be sure about—for instance, as to whether the child saw and heard. In a very early stage after convulsion he had seen several cases in which he was satisfied that the child neither saw nor heard. But when the child ceased convulsions it was his experience that it showed no interest in anything going on around it. It might remain in that stage for several days, or even a week, and then he had seen several children that had passed into a state of peculiar whining, making an unceasing cry all the time they were awake. That might persist for the best part of a week, after which it gradually diminished. That was the first sign in some cases of returning consciousness on the part of the child. After that it began to show some other signs of taking notice, but even for weeks one might have the fear that the child was going to be left an imbecile. He had two cases in which the speech was the last thing to recover. Dr. E. STOLKIND mentioned nervous complications following paratyphoid fever; these, he said, were found in many cases, as in typhoid fever.

Dr. KINNIER WILSON, in summing up the discussion, asked what, after all, they had been trying to classify. In any fever, if it was a diffused condition, one might get any complication. There could be nothing significant in having occasional nervous symptoms. Dr. Rolleston had emphasized the extreme rarity of these phenomena. Why did they not occur more often? If one had a diffused condition of any kind the nervous system could only react with what it had got—namely, its own relatively few tissues. He was delighted that Dr. Wyllie should have made an attempt at a pathological description, and even more delighted that the pathologist who followed him refused to accept it, because the first thing that Dr. Greenfield did was to point out that these were not diseases at all, but merely pathological processes, and that more than one pathological process could exist in the same condition. That was true of the various forms of encephalitis. A remarkable feature of the discussion had been that not a single question had been addressed to the three openers, and therefore there was no need to call upon them to reply.

IRRADIATION OF GROWTHS

At a meeting of the Devon and Exeter Medico-Chirurgical Society, held on February 22nd, Dr. C. WROTH read a paper on "Types of Growth which are Suitable for Irradiation." Dr. Wroth said that an x-ray department should not refuse the treatment of any case so long as there was a possibility of cure, however meagre that possibility. As an instance which encouraged one not to give up hope he quoted the case of a growth originating in a retained testis and offering a particularly bad prognosis. A secondary growth had appeared in the remaining testicle, and metastases were disseminated all over the abdomen. Yet here was a man, almost moribund in 1925, who had responded so well to x-ray therapy that he was now, to all outward appearances, in a sound condition of health. As regards the mode of action of x rays and radium the stimulating effect on a growth was, in his opinion, so slight as to warrant ignoring it for all practical purposes, although certain rare cases did arouse suspicion. To the destructive effect of irradiation had been assigned two modes of action: (1) direct, by modifying the activity of the individual cell; and (2) indirect, by action on the stroma, and thus limitation of the blood supply. The consensus of opinion gave equal importance to each of these actions. Strangeways of Cambridge had shown that with heavy irradiation only a few cells could

be killed. Canti and Donaldson, with cinematograph films of cultures, with exposures taken at intervals of one hour, traced the cells most damaged by irradiation, and found that they were those immediately about to divide. A direct selective action found proof in experiments, one of which was the action on ram's testicles when, three months after exposure to irradiation, the general health of the animal was good, the testicles sound, and the ram virile, although lacking in spermatozoa. Dr. Wroth then showed radiographs of a growth in the femur, secondary to one in the mamma, where selectivity was manifest in the rapid shrinkage and final sclerosis of the tumour. The destructive effect, as observed with experiments on chick embryos, was more powerful after life had been established for six days than it was at twenty-four hours, and this might be explained by the strangulation of vessels by fibrous tissue.

Radio-sensitivity affected normal tissues in the following diminishing order: (1) lymphoid tissue, (2) leucocytes, (3) ovary and testis, (4) skin, (5) salivary glands, (6) digestive glands, (7) central nervous system and nerves, and (8) connective tissue. The type of patient, whether with a moribund appearance or non-cachectic, gave no particular guide as to prognosis, nor was there any true relation between sensitivity and curability. Rapidly growing tissues were more radio-sensitive than the reverse, and secondary growths in glands were more resistant than the primary tumour. Discussing the reasons that could be adduced for the resistance experienced in treating "recurrences at site," Dr. Wroth mentioned: (1) that the tumour bed was damaged already, and that little, if any, further action could be expected on the blood vessels of the area; (2) selective action had been completed already, and resistant non-sensitive tissues represented the remaining activity; and (3) situation was also a factor—for example, a carcinoma of the palate had been seen to disappear, whereas a similar type of growth in the fauces was more resistant. Again, a carcinoma of the cervix was more sensitive than one on the vulva. The lower lip was radio-sensitive, although the growth was slow. Secondary infection had a marked influence in reducing the activity of a growth, and experiments were being directed on the action of dyes. As regards types of tumours, a carcinoma of the breast was not especially sensitive or responsive, but, on the other hand, the secondary growth was occasionally responsive, and in the U.S.A. a few doses of irradiation had been found useful when given in advance of the operation with the idea of discouraging metastases. In Stockholm 40 per cent. non-recurrences were claimed by this means.

Dr. Wroth then touched briefly on the technique of the application of x-ray therapy and radium. With radium the time factor was important, and one-half the total dose given in thirty-eight days had proved more effective in producing sterility than an intensive dose, which was liable to produce necrosis. It was generally agreed that it was worth while following up the treatment of inoperable growths of the uterus with x rays after local treatment with radium. With the tongue radium had given good results, but it was a question as to the advisability of glands being dissected out surgically in association with local treatment. Growths of the lip might prove radio-resistant, and were otherwise easy of removal by surgical means. While the palate responded well to radiotherapy the throat and fauces were resistant in the same measure. So-called "radium seeds" were used in treating growth of the tonsil, fauces, and bronchus, but were inactive after twenty days. Poor results were experienced with the pharynx, and they were poorer still with the extrinsic larynx. Radiotherapy of the rectum had been practically abandoned owing to the persistent radio-resistance experienced. Rodent ulcer responded well to radiation (gamma rays), tumours of the skin being radio-sensitive as a rule. Bad results attended radiotherapy of the bladder and kidney. Tumours of the prostate were likewise resistant. The embryonic round-celled sarcoma responded well to treatment, while, on the other hand, sarcoma of bone was very resistant. Seminoma of the testis was very radio-sensitive, but the pituitary body was not responsive; in eosinophilic adenoma of the latter one might attain arrest with

cessation of headache, but more than that one could not expect. Dr. Wroth had seen an unexpectedly good result follow x-ray therapy in cerebral glioma. In his experience tumours of the thyroid responded very badly if the treatment followed an attempt at surgical extirpation in the first instance, and he advocated radiation of the virgin tumour, or not at all. Cavernous naevi, warts, etc., were radio-sensitive, and good results could be expected if the growths were taken early. Turning to tumours of the chest, an endothelioma of the pleura had proved sensitive, but carcinoma of the bronchus offered a very poor outlook. He then showed radiographs illustrating the treatment of malignant stricture of the oesophagus, and contrasted the hopeful results now obtained by the new method of large doses of x rays, as compared with the disheartening effects of previous methods.

The PRESIDENT remarked that the Royal Devon and Exeter Hospital (where the society had met together) was one of the very first institutions to install plant for deep x-ray therapy, and that in addition the hospital was in possession of a good supply of radium.

Mr. WAYLAND SMITH also emphasized the paramount importance of a working liaison between the radiologist and the surgeon. He agreed that growths of the oesophagus had proved a bugbear to all concerned in their treatment in the past, but hoped that the recent advances mentioned by Dr. Wroth would prove the means of materially bettering the prognosis. In keloid growths, resulting from burns of severe degree, he had seen good results from superficial x-ray treatment, or from removal of the keloid surgically and then treating the scar area, whilst paying due regard to the tissue lying beneath that area.

Mr. CHARLES CARROLL mentioned a case of nasopharyngeal fibromata which had proved obstinate to radiotherapy and all attempts to obliterate them surgically. Recently, they had recurred, and sprouted through the hard palate. Mr. A. L. CANDLER asked what was happening, and what should be our further course, when severe constitutional symptoms followed deep x-ray therapy. He also asked if the associated symptoms were rendered more severe when an artificial menopause was produced by radiotherapy in a case of fibromyomata. In his reply Dr. WROTH said that the condition mentioned by Mr. Candler could be accounted for by shock and toxæmia. He added that the menopause so produced was an effect on the ovary and endometrium, but that irradiation had no direct result on the fibromyoma itself. The associated symptoms were likely to be more severe if the menopause was produced at an abnormally early age. The case quoted by Mr. Carroll seemed to be an example of a condition stimulated by irradiation.

PYURIA IN THE PUERPERIUM

At a meeting of the Edinburgh Obstetrical Society, held on February 14th, with the president, Dr. OLIPHANT NICHOLSON, in the chair, Dr. DUGALD BAIRD read a paper on "Pyuria in the Puerperium."

Dr. Baird began by stating that, following parturition, infection of the urinary tract occurred frequently. In a series of 717 women, in whom the urine was sterile before delivery, gross infection of the urine developed in seventy-nine cases (11 per cent.). After spontaneous delivery the incidence was 5 per cent., and after complicated delivery 25 per cent. Where the pyrexia was notifiable the incidence of pyuria was much greater. In the analysis of a series of 3,600 consecutive deliveries it was found that infection of the urinary tract accounted for about 12 per cent. of all cases of puerperal pyrexia. Exact diagnosis of the cause of the pyrexia was very difficult in some cases. About half the cases of pyrexia of urinary origin were due to exacerbation of chronic pyelitis of pregnancy or to continuation of pyrexia of acute pyelitis of pregnancy. The rest resulted from infection occurring in women in whom the urine was sterile before delivery. In thirty-six cases the pyrexia was septicæmic (8.1 per cent. of the total cases of pyrexia), and of these eighteen were due to coliform organisms. In this latter group the urine usually became infected

and the symptoms were those associated with pyelitis of the puerperium—namely, remittent fever, rigors in 56 per cent. of cases, urinary symptoms in 38 per cent., usually very slight and of short duration, and abdominal discomfort and distension. Predisposing factors were difficult delivery and albuminuria of pregnancy. In 52 per cent. of cases the time of onset was before the third day, and in 34 per cent. the eighth day or later. In over 50 per cent. of cases an organism, identical to the one in the blood, could be isolated from the faeces. It seemed likely that the organism usually spread to the vagina over the perineum and by means of lacerations to the blood. These cases had been termed septicæmia, because the organisms were demonstrated repeatedly in the blood stream, and as soon as the blood cultures became negative the temperature fell. Stasis was rarely found in the ureters in these cases, and the urinary infection which was produced cleared up quickly. Pyelitis of the puerperium could be differentiated into two groups: (1) exacerbation of a pre-existing infection, and (2) primary infection in the puerperium. As a rule, in Group 1 the pyrexia occurred just after delivery and settled down quickly. In Group 2 the pyrexia usually came on later in the puerperium. Seventeen per cent. of puerperal women were found to have residual urine, which might have become infected, and result in ascending infection.

Blood Pressure and Decubitus

Dr. BARCLAY DICKSON read a paper in which he said that while carrying out a certain treatment on women in the later months of pregnancy it was noticed incidentally that the blood pressure taken with the patient lying on her back was appreciably higher than with the patient lying on her side. Neither treatment nor time had anything to do with the difference, as the two pressures were taken within a couple of minutes of each other, immediately after treatment. The preliminary investigation was done on two patients suffering from pre-eclamptic toxæmia. It now remained to find out if the same difference in the two pressures, back and side, occurred in all cases, pregnant or non-pregnant, man or woman. A series of thirty cases was examined in the Royal Maternity and Simpson Memorial Hospital, Edinburgh, the series including two males. The rest of the series was taken indiscriminately from the wards. The total average difference in the systolic pressures was 10.9 mm. Hg, and the total average difference in the diastolic pressures was 12.15 mm. Hg, in both cases the side pressure being the lower. Since a difference in the two pressures was obtained whether pregnancy was present or not, the cause of the difference could not be solely a mechanical one, due to the compression of the aorta by the pregnant uterus. It was therefore thought to be due to a stimulation of the sympathetic plexuses connected with the thoracic and abdominal arterial system by the weight of the viscera—heart, lungs, and gastro-intestinal tract. This stimulation would naturally come into force only when the patient lay on her back, and would cease on her taking up the side position. That injurious stimulation did not occur was indicated in nocturnal incontinence of urine and nocturnal emissions. Both conditions occurred mostly when the patient was lying on the back, and both conditions had been cured when the patients were forced to sleep on the side. There was evidence to show that in hyperpiesis the diastolic difference—the difference between the back and side diastolic pressures—was very small; in one case quoted it was only 4 mm. Hg, and the patient died later from cerebral hæmorrhage. The average diastolic difference in the above series was 12.15 mm. Hg. Dr. Dickson wondered if it might be possible to use the diastolic difference as an aid to immediate prognosis in any given case of hyperpiesis of whatever origin.

Corrigendum

In our report last week (p. 499) of the discussion on hæmatemesis, at the Royal Society of Medicine, the remarks of Mr. John Morley of Manchester were attributed in error to Mr. A. S. Morley.

CORRESPONDENCE

Silicosis and South Wales Colliers

SIR,—In your issue of March 10th (p. 452) Professor J. S. Haldane suggests that the importance of silicosis as a disease of South Wales coal miners, is greatly exaggerated, and rejects the "great majority of the diagnoses of the medical boards."

In 1930, writing on coal-miner's lung, in the *Journal of Pathology and Bacteriology*, we published figures of the pathological, histological, and chemical findings in thirty-four persons, divided into three clinical classes as follows:

Class A.—Twelve coal miners dying of chronic pulmonary disease after long disablement.

Class B.—Sixteen coal miners dying from causes other than chronic pulmonary disease and not known to have any pulmonary disablement.

Class C.—Six other industrial workers as controls.

The "total silica" values for these groups, as set forth in our table, may be summarized as follows:

	Total Silica in Grams	Silica percent- age of Dried Lung	Silica per cent- age of Ash of Lung	Ratio of Combustibles to Silica
Class A ...	9.4	2.56	27.1	38 to 1
Class B ...	4.4	1.24	16.3	71 to 1
Class C ...	0.29	0.13	2.4	720 to 1

It will be seen that the lungs of coal miners, as a group, contained a very much greater amount of "total silica" than those of the "other industrial workers," the advanced cases in Class A that had lived on to the dyspnoic stage showing figures entirely comparable with those of fatal cases of silicosis in South Africa, while the colliers who had died of intercurrent causes before reaching the dyspnoic stage still exhibited a markedly abnormal amount of "total silica" in their lungs. From the clinical point of view the reports of cases of silicosis in the South Wales coalfield by Dr. N. Tattersall (*Journ. Indust. Hyg.*, 1926, viii, 466) and of the medical staff of the King Edward VII Welsh National Memorial Association (*ibid.*, 1931, xii, 19) appear to establish the existence of a condition corresponding to silicosis in South Wales. That the inhalation of coal dust alone, even in its hardest variety, anthracite, fails to produce any serious degree of lung fibrosis is rendered probable through specimens and analyses in our possession, and has recently been established, on radiological grounds, by the report of the Industrial Lung Committee (*British Medical Journal*, February 3rd, 1934, p. 198).

While medical boards are not infallible, it must, we think, be admitted that the inhalation of the stone dust to which the coal miner is exposed in South Wales is capable of leading, in many cases, to a state of lung fibrosis which, depending as it does on silica, free or combined, is most conveniently described as "silicosis." Whether the silica causing this condition is "free" or "combined" remains an important question for future investigation, but does not matter much to the working collier. Professor Haldane considers that "if there were actually a large number of cases of real silicosis... among South Wales colliers their phthisis death rate would be considerably increased above a normal figure." To this we would reply that Professor Haldane himself has pointed out that "it is difficult to resist the conclusion that, in some way, the inhalation of the dust in coal mines tends to prevent phthisis." It is to some such preventive action of coal dust that the low tuberculosis death rate in colliers may yet prove to be due, and we cannot accept

unreservedly the proposition that silicosis inevitably must terminate in obvious tuberculous phthisis.

We think that Dr. W. R. Jones has made out a very good case for the role of sericite in the production of "silicosis," and his views, if confirmed, will explain many points now obscure in connexion with the aetiology of the disease.—We are, etc.,

Sudden Circulatory Failure in Diabetic Coma

SIR,—The recent letters of Drs. Fuller and Himsworth (p. 405), Douthwaite (p. 353), and Towers (p. 456) rightly emphasize the importance of treating circulatory failure in diabetic coma. Admittedly, as Dr. Towers states, the myocardium may be functionally impaired in severe diabetes, yet available evidence points strongly to peripheral vascular rather than cardiac failure in diabetic coma. Low blood pressure, pallor, coldness, small contracted veins, and a concentrated blood indicate vaso-motor paralysis and loss of fluid from the circulating blood volume, with consequent failure of the venous return to the heart.

The correct treatment of this peripheral vascular failure should consist of warmth, elevation of the foot of the bed, intravenous injection of fluid, and vaso-constrictors. Warmth is best provided by a hot air bath or electric blanket. As Dr. Graham has pointed out, estimation of the haemoglobin is the best index of concentration of the blood and of the need for fluid, which should be administered slowly by the intravenous route in the form of saline or hypertonic glucose. Ephedrine 1/2 grain or not less than 1/12 grain of strychnine injected may improve vascular tone. The importance of the horizontal posture, with elevation of the foot of the bed, has been adequately stressed by your correspondents.—I am, etc.,

London, W.1, March 12th.

D. EVAN BEDFORD.

Colonic Irrigation

SIR,—A letter on this subject by Miss MacManus in your issue of March 10th (p. 459) certainly calls for remark by our profession. Personally, I feel deeply gratified that an authority of such eminence among our nursing colleagues has delivered such an exhortation. It prompts me to contribute the following.

After receiving a three-pint Plombières douche in the morning, an elderly subject was taken with abdominal pains the same afternoon. These persisted, and pyrexia, with an increased pulse rate, followed. Three days later a gangrenous appendix was removed.

A patient was admitted by a house-surgeon as suspected acute intestinal obstruction. He ordered a turpentine enema, which, when I operated a few hours later, had found its way into the peritoneum. This was obvious from the odour and character of the free fluid present. Obviously, the route of entry was through the perforated gangrenous diverticulum of the sigmoid colon. I have no doubt that the enema had seriously hastened the woman's end. In another fatal diverticulitis case, on which I operated a fortnight ago, I cannot escape from the feeling that the same pitiable sequence of events ensued.

Not rarely do patients who have had a colonic resection receive rashly administered saline injections or enemata within a few hours or days of operation on the bowel. Such have led to fatal leakage. In this connexion, an article by Petty, in the *Journal* of September 9th, 1933

(p. 491), is a pointed illustration. This contains a careful study of two cases of appendicectomy, followed by death, where enemata were suspected to have been responsible for leakage at the appendicular stump, about which site virulent peritonitis was found to have developed after operation. Further, relevant too is the reference to the article by Rayner (*British Medical Journal*, 1932, i, 419), wherein are ably described the misadventures possible even by the insertion of a nozzle into the rectum. Grave results and even death have ensued therefrom.

The recital of such disasters makes a formidable array of dire dangers, founded on fact, coming instantly to the mind of one surgeon. Let this be multiplied by the wider experience of the whole profession, and it will be understood how readily I seized the opportunity afforded by Miss MacManus's letter. It is vital to voice the feelings of a surgeon that not only should such valuable therapeutic and diagnostic measures be kept strictly to the trained nurse, but that still more careful instruction should be given to our nursing and medical students in this sphere of their work.—I am, etc.,

A. WILFRID ADAMS, M.S., F.R.C.S.

Bristol, March 13th.

A Milk Ration for Children

SIR,—Dr. R. L. Kitching (March 17th, p. 505) asks me for the source of the figures quoted by me in my letter to the *Times* of March 5th. They were derived from a brochure with the title "The Nation's Milk Supply," published by the United Dairies Laboratory Department last July, with an introduction by Professor W. W. Jameson, director of the London School of Hygiene and Tropical Medicine. This brochure has been widely circulated among members of Parliament. I was abroad at the time of writing my letter, and had no opportunities of confirming its statements by independent inquiry. The pertinent sentence runs as follows:

"Out of a series of 43 herds (that is, 'the super-herds of the country coming under the grading and licensing authority of the Ministry of Health'), samples of certified or Grade A tuberculin-tested milks were reported upon: 33 of the samples, that is, 76 per cent., contained haemolytic mastitis streptococci, and 27 of the 43 samples, that is, 62 per cent., revealed the presence of the *Brucella abortus* bacillus."

Further data with which I have been furnished since my return to London confirm my conviction that protection against other infections than tubercle is not in any way secured by the preparation as at present practised of certified and Grade A (T.T.) milk. That was the argument of my letter and the explanation of the amendment which I moved at the meeting of the Children's Minimum Committee, without, however, securing its adoption. You, Sir, in your admirable leader of February 24th, supported my contention. You wrote:

"That a large amount of disease is carried by raw milk is no longer an opinion; it is a fact—a fact as well attested as any in the domain of medical science. The recommendation, therefore, that milk should be consumed in the raw state is equivalent to the support of a measure which must result in the occurrence of sickness and death among a proportion of those affected by it."

Incidentally, I must differ from Dr. Kitching when he says that—"it is the duty of the medical authorities to prescribe what is best [that is, certified milk] regardless of cost." That would surely be a futile gesture on the part of the medical profession. At the present time less than 1 1/2 per cent. of the milk consumed in this country is of this quality. The figures quoted by me dealt with this section only. Does Dr. Kitching really suggest that the Bill which may come before Parliament as a result of the present agitation for supplying milk to school children should insist upon the milk being of "certified" quality? Much unwitting

harm is done by facile philanthropists who demand action without any consideration whatever of its cost or its ultimate repercussions. It is forgotten, for example, that an increase of the dole, which is now being pressed upon the Chancellor of the Exchequer, must result in increase of taxation, and increase of taxation automatically produces an ever-widening circle of unemployment, thus defeating the whole purpose of the pressure.

I think I sufficiently answer Dr. Kitching's points by the statement, which I submit is implicit in your leader, that under present conditions milk can only be rendered safe by some form of heat treatment. Clearly it is desirable and even essential to supply a clean milk. Indeed, I see no reason—and this is the opinion also of the largest milk producers in this country—why the supply of what Dr. Kitching calls "ordinary ungraded filth" should not be made a penal offence, just as the supply of unwholesome food is a penal offence. The grading system, by offering a premium for "clean" milk—a premium which, indeed, is so high as to render it available only to a minute fraction of the population—seems to me to attack the problem from the wrong angle. It has been demonstrated that with comparatively little expenditure the quality of milk can be improved to a marvellous degree by exercising surgical cleanliness in production and distribution. I am convinced that advance lies upon these lines rather than upon reliance upon the very expensive present procedure, which in practice offers little or no real protection.—I am, etc.,

House of Commons, March 19th.

E. GRAHAM-LITTLE.

The Milk Question

SIR,—I am surprised that no comment has appeared in reference, to the leading article in your issue of February 24th on the milk ration for children. This week there is a note that the Minister of Agriculture proposes to devote certain funds for the provision of pasteurization plant, and under "Ireland" appear some facts in regard to tuberculous infected milk, the most significant points being that in Scotland 2.8 per cent. of pasteurized milks contained living tubercle bacilli, and that in a number of samples of Certified and Grade A (T.T.) milk a percentage of 0.14 was found.

In your leader it is stated that to agree in the consumption of raw milk is to support a measure which is bound to cause sickness and death, and that the only means to ensure a safe milk is treatment by heat—either pasteurization or boiling. If it had been stated "raw milk as it is produced to-day" I would agree, but as it stands the statement is a gross exaggeration, and that the only way to render milk safe is heat treatment is by no means a fact. Considering the thousands of gallons of raw milk that are consumed, and that a very high percentage (say over 80 per cent.) is contaminated, the relative amount of disease directly traceable to milk is small. It is surely reasonable to assume that if the contamination was reduced by, say, 90 per cent., the amount of disease would not only be correspondingly reduced but would practically disappear, as, under present conditions, the actual origin of a fairly high percentage of disease attributed to milk infection is only presumption, and not actually proved. Every case of bovine tuberculous disease does not necessarily arise directly from milk infection.

I am certain that the first, and indeed the only, public health consideration in the matter is not pasteurization but the application of conditions and methods which will ensure a clean raw milk. It has been repeatedly shown that these conditions and methods can be carried out at practically no expense to the producer, and they

certainly do not entail more being done than the manufacturers of foods much less liable to the contamination than milk are called upon to do. The large cities already obtain milk which is of fairly good standard, and pasteurization is carried out only for commercial reasons. Anyone acquainted with the process knows that a high degree of purity is essential in the raw product to ensure efficient pasteurization, but still better productive measures would reduce the pathological organisms to such a degree that it would be extremely difficult to prove that any sample actually caused disease. The country districts require the greatest consideration, as it is practically impossible to pasteurize all the milk consumed in them; compulsory legislation could only be applied, therefore, in the large urban areas, and we cannot conceive of legislation which would discriminate in a matter of public health dealing with the purity of food between one part of the population and another. It must be remembered, too, that even if it were applied in urban areas pasteurization would not ensure that the inhabitants will always drink treated milk—thousands of families migrate to the country every year, and make a special point of drinking milk straight from the cowshed. As for boiling milk, despite the efforts of generations of doctors, few families practise it, and in the country districts it is safe to say that none at all do.

It may be contended that only the milk ration is being mentioned, but here is the opportunity of dealing with the whole question which may never occur again, and it must be grasped. In regard to tuberculous infection I am convinced that the tubercle bacillus enters the milk in the vast majority of cases not directly from an infected animal, but indirectly from contamination with dung, etc.; 99 per cent. of other pathological germs gain entry from the same source, and all are preventable by the easiest of means. To mention epidemics is misleading—these can only be regarded as accidental, as in the case of water supplies—and if milk is so dangerous why do we not have more epidemics than we do? Tuberculin-reacting animals and their milk should be dealt with by the method advocated by Dr. Savage. The protagonists of raw milk are concerned with much more than vitamins, and there are many good reasons why we should be able to obtain clean raw milk. At the same time, I am not decrying pasteurization *per se*; but to advocate compulsory measures without primarily insisting on clean milk is an error of the first magnitude.—I am, etc.,

Hounslow, March 12th.

W. S. FORBES.

Prevention of Influenza

SIR,—Dr. J. Torrens's paper in the *Journal* of February 17th (p. 274) has renewed interest in the disease known as influenza, but I am writing this because it seems to me that the origin of the disease has been lost sight of, and the efforts to find protective measures have been carried in the wrong direction.

If you refer to the older works on medicine you will find the disease was spoken of as "Russian influenza"; and this because in the earlier epidemics it always appeared first in Russia, so far as Europe was concerned. Later epidemics made their first appearance in the South of Europe. This points to the disease originating in the Far East, the infection in the earlier epidemics travelling by the trade routes across Asia, and in the later ones, coming more speedily by boats through the Suez Canal. You will recall that the epidemic of 1918 was popularly known as "Spanish influenza," because in Europe it appeared first in Spain. This variation was due to the fact that the Suez Canal was not so much used during the war, and the boats were arriving from the East via the

Cape. The disease was spreading in South and West Africa before it reached Europe. All these points support the theory of the Oriental origin of the disease.

In the autumn of 1889 we read in the papers accounts of the floods in China caused by the overflowing of the Yellow River (Hoang-Ho), and it was soon after the subsidence of these floods that we heard of the epidemic commencing in China. In 1918 the papers were too full of war news to say much about floods in China, but I ascertained that such had occurred in the early part of the year. Now the Yellow River, as we all learnt at school, has earned its name by the circumstance that it brings down large quantities of yellow mud. This is held in suspension in the upper reaches, where the current is strong, but as the river widens towards its mouth the current is slower and the mud is deposited, so that a bar is gradually built up. Then comes the time when the river is in spate, the current is obstructed by the bar, and a vast flood results. Presently a channel is washed out, the floods subside, and all goes well until another bar is built up. It seems likely that the infection is contained in the mud left deposited on the land, and on drying up is scattered in the form of dust. Here we have the explanation of the fairly regular recurrence of the epidemics some twenty-eight or twenty-nine years apart; and one can predict that the next visitation may be expected about 1946 or 1947. I see that Dr. Torrens puts it between 1945 and 1955.

It seems curious that in the case of such a widespread and common disease all research has been very unsuccessful. But, after all, suppose the research were highly successful, and produced a perfect protective vaccine, how much good would result from it? You cannot protect the whole world—you cannot protect even this country—by such means. Any attempt to do so would be met at once by the usual opposition of the "anti" party, and if left to voluntary initiative would be neglected until too late to make any real difference. Protection, to be of any use, must go further back and strike at the origin. The dredging of the river would seem to be the solution of the problem. It is a big river; and it would be a big job to keep it clear, but not too big for modern engineers to accomplish. The cost, too, would be big, but, after all, it is one to which the whole world should contribute. What is the cost of an epidemic to each country in lives, in loss of working days, and for years after in pulmonary and nervous diseases that follow in its train? A comparatively small amount from each of the Great Powers would be enough to carry out the work, and, I think, would prove to be a sound investment. But we cannot rely on having more than about twelve years before the next epidemic arrives, so that if anything is to be done in the way indicated a start should be made without delay.—I am, etc.,

London, W.I, March 5th.

HOWARD WISE.

Rupture of the Liver in the Newborn

SIR,—In your issue of March 17th (*Epitome*, para. 225) it is stated: "Eva Holmberg (*Finska Läkarsällskapets Handlingar*, November, 1933, p. 1067) notes that, before 1918, when Hedrén published in a Swedish journal his paper on fatal injuries to the abdominal organs in the newborn, no systematic study had been made of rupture of the liver." May I point out that more than twenty-seven years before Hedrén's communication, in a paper read before the Obstetrical Society of London and published in vol. xxxiii of that Society's *Transactions* (1892, pp. 203-296), I made such a systematic study of injuries to the liver and other viscera in

the newborn, and illustrated the injuries by drawings? Among the 150 newborn foetuses there were three cases of rupture of the liver, in two the rupture being confined to the capsule and giving rise to extensive haemorrhage into the peritoneum; in addition, there were thirty-seven subcapsular haemorrhages (illustrated). In Hedrén's "over 1,000 necropsies" three ruptures occurred; in Holmberg's "over 1,000 necropsies" ten ruptures and thirty-seven subcapsular haemorrhages were observed. The author, in a bibliography of the literature "to which she had access" (i den mig tillgängliga litteraturen), does not mention my paper. May I once more call the attention of obstetricians and gynaecologists to the value of the complete index published in the forty-ninth volume of the *Obstetrical Transactions* in providing references to work done in the last forty years of last century?—I am, etc.,

London, W.I, March 18th. HERBERT R. SPENCER, M.D.

Toxins and Emulsions.

SIR,—In reply to the letter of Dr. G. Norman Myers, published in your issue of March 17th, we were totally unaware of any thesis on this subject submitted by Dr. Myers to the Board of the Faculty of Medicine of Cambridge University, and we had no knowledge that Dr. Myers was engaged on this work, which he says he began three years ago, in collaboration with the late Professor W. E. Dixon. Since the appearance of his letter we have obtained the abstract of his thesis, which we find is entitled "Experimental Investigations on the Action of Digitalis and other Drugs in Toxaemia"; it was published in August, 1933. The only reference in the abstract of his thesis having any bearing on emulsions is the following:

"Olive oil, when mixed with aqueous solutions of superlethal doses of diphtheria toxin so as to form an emulsion, protects animals from the lethal effects of the toxin when the emulsion is injected subcutaneously. Olive oil also protects against the effects of superlethal doses of the toxins of *B. tetanus*, *G.G. welchii*, and the *Vibrio septique*. Liquid paraffin has a similar protective action against lethal doses of these toxins, but cream of cow's milk affords no protection."

The observation, that superlethal doses of toxins mixed with finely divided emulsions were non-toxic when injected subcutaneously, was first made by us in 1928, and the whole of the experimental evidence quoted by us in our paper was completed in this laboratory in 1930. Before beginning our clinical investigations this observation was confirmed by workers at the Lister Institute and by Dr. A. B. Porteous at St. Mary's Hospital in 1930. Three years ago one of us (V. G. W.) communicated these results to the Medical Research Society at its meeting in the Pathological Institute of St. Mary's Hospital, when the apparatus for the production of the finely divided emulsions used in this work was also demonstrated, and reference was made to specific adsorption of toxins, which work had been carried out in conjunction with Dr. Grist. In 1930, on the evidence we had obtained showing that toxins were adsorbed and rendered non-lethal when mixed with finely divided emulsions, Sir Leonard Rogers requested that a supply of hydnocarpus emulsion should be dispatched to workers in India, which was done. At the same time Professor Lyle Cummins was supplied with cod-liver oil emulsions for some work on tuberculosis, which has since been published.

It is clear that Dr. Myers unwittingly repeated experiments with emulsions which had already been completed before he began his work.

Dr. Myers states in his letter: "The oils and fats were mixed with aqueous solutions of lethal doses of the toxins so as to form emulsions, which were injected subcutaneously into animals." A solution of toxin in water does not form a spontaneous emulsion with oil, so that Dr. Myers's phrase "so as to form an emulsion" must mean mechanical agitation. As Dr. Myers has mixed his toxins with the continuous phase prior to the formation of the emulsion, which must entail agitation, we suggest that his non-toxic results were due more to destruction of toxin, through oxidation than any other cause. This source of error we meticulously avoided.

Dr. Myers also writes: "I have also established that these toxins have a greater solubility or affinity for water than for the oil, even when they are mixed in the form of an emulsion," and previously he says in his letter that emulsions protected against 24 m.l.d. of toxin. It follows, therefore, that there were more than 12 m.l.d. of toxin in the water unless the emulsions contained more than 50 per cent. of oil. If the animals injected did not die under these conditions his results certainly border on the miraculous. Apart from this we cannot agree with this statement, for we claim this phenomenon to be one of physical adsorption and not a question of solubility. It is for this reason that coarse emulsion—or, as Dr. Myers points out, "cream from cow's milk"—affords no protection, as sufficient adsorption does not occur with such large particles.

Another of Dr. Myers's statements reads: "My results have definitely shown that the oil of these toxin-oil emulsions is very slowly absorbed from the tissues after subcutaneous injection, accompanied by a slow liberation of the toxin." Does Dr. Myers wish us to believe that the large amounts of toxin, which he says are present in the water, are also slowly absorbed? If so, this is contrary to all the experimental knowledge of the absorption of substances in solution from the tissue fluids. We would further like to point out that Dr. Myers does not state either in his abstract or in his letter the percentage of fats contained in his emulsions, or the amount of emulsion injected with his lethal dose of toxin.

The adsorption of toxin by $1\frac{1}{2}$ c.cm. of 3.5 per cent. olive oil emulsion *in vitro* suggested the possibility of adsorbing circulating toxins in the body by increased dose and concentration of olive oil emulsion injected intravenously. During the last four years work has been carried on both experimentally in this laboratory and in various clinical centres both in this country and in India. We are investigating the use of emulsions intravenously in toxæmia of infective, biochemical, and traumatic origin in adults and in infants, and our results, which will shortly be published, are distinctly encouraging. In addition, we might point out that during the last four years clinical experimental work has been in progress whereby tuberculin and other vaccines have been given with our finely divided emulsion with a view to rendering them non-toxic. Further, bacteria of all varieties have been brought into solution, thereby rendering their toxins capable of being adsorbed on to finely divided emulsions.

In conclusion, we definitely assert that, quite apart from the fact that our experiments were concluded and publicly discussed before Dr. Myers began his investigation, the phenomenon referred to by Dr. Myers in his thesis can be very largely explained by the well-known destruction of toxin by oxidation. It is thus clearly apparent that Dr. Myers's experiments deal with an entirely different subject from that of physical adsorption of toxin on to already formed fine emulsions discussed

in our paper. We cannot under any circumstances admit, as Dr. Myers suggests in his letter, that our paper confirms his earlier findings, nor do we admit that the statements made by Dr. Myers in his letter or in the abstract of his thesis in any way confirm what we have demonstrated.—We are, etc.,

Hospital Medical School,
March 19th.

V. G. WALSH.
A. C. FRAZER.

SIR,—With reference to your correspondent's letter on toxins and emulsions, the work quoted on this subject by Drs. V. G. Walsh and A. C. Frazer in the *British Medical Journal* of March 10th was conducted in my laboratory and completed in 1930.—I am, etc.,

Physiology Department, St. Mary's
Hospital Medical School,
March 19th.

B: J. COLLINGWOOD.

Hypochondriasis

SIR,—The instructive and also humorous lecture on hypochondriasis (*Journal*, March 3rd) by Dr. Robert Hutchison well merits consideration. Under the heading "The Crank" (p. 365) we read: "It will be time to deal with the laity when we have purged our own profession of faddery," apparently an indefinite postponement of the time when the laity shall be instructed on this matter. This is emphasized by the writings of a well-known psychologist, who expresses his opinion in these words: "The problems of physical health and the education of the general public in matters of hygiene would seem to involve, first of all, the conversion of doctors as a whole to a new attitude of mind, based upon a knowledge of motive and the principles of psychopathology, rather than upon the more material foundations of anatomy, physiology, and pharmacology." Is this "conversion" taking place, and is it desirable? The interests of our patients surely claim a reply in the affirmative.

A busy practitioner may only too possibly, in the rush of work, arrive at the stage of giving the "placebo" without applying the excellent advice with which Dr. Hutchison forestalls his suggested treatment of the "general hypochondriac" (p. 365)—namely, listen patiently, examine thoroughly, etc. In the instance given under "Filial Hypochondriasis" (p. 367) surely "father" is aware of his liability to bronchitis, his cardiac disability, his tendency to undue excitement at his evening games, but does not use his strength of will to overcome his desire for these, presumably, harmful procedures: an all too common experience of humanity. Would not the solicitous efforts by persuasion of some member of his family be of actual help to him? Without undue temerity, I hope, might one suggest that, while being aware of the activities of "faddery," we do not include in that term the ascertained results of scientific research regarding diet, sunlight, ventilation, etc., each of them valuable aids when correctly applied—in other words, that we do not "tip out the baby with the bath water."

If by drawing attention to Dr. Hutchison's lecture, with its sound sense and reasonable ideal, some appreciation and practice of the meaning expressed in his last paragraph could be induced, then Sir George Newman's dictum "Health is won by a way of life rather than by a bottle of medicine" would often be verified. Perhaps this, too, needs the "conversion of the doctors"!—I am, etc.,

W. W. SHRUBSHALL, D.P.H.

Burgess Hill, Sussex, March 12th.

SIR,—Dr. Hutchison's address (March 3rd, p. 365) is most stimulating, but why is he so pessimistic as to the possibility of treatment? Why is it "useless" to "attempt to cure" the general hypochondriac? Dr. Hutchison begins by defining hypochondriasis as "over-anxiety"—about health. Well, Sir, are the anxiety states so difficult to treat if we recognize what is the *real* cause of the anxiety? But is it usually at bottom health about which the patient is really anxious? I venture to suggest that it is not, and that the health propaganda which Dr. Hutchison deplors merely serves as a convenient channel for the expression of anxiety due to other causes.

The mention of the "antiseptic baby" recalls the patient described by, I think, the late Dr. Rivers—a lady who, during the war, *expressed* no fear for her husband at the front, but found no precautions too elaborate to protect the health of her two children. When, however, the news came that her husband was killed the nursery routine went back to normal. Dr. Hutchison would presumably call this a case of vicarious hypochondria; but is it not obvious that the fear which she refused to admit for her husband had transferred itself to the children?

If the real cause of anxiety is not usually to be found in the sphere of health, where are we to look for it? The middle-aged man who has given up business, or the colonel who has retired from the Army, is not occupying as important a situation or receiving as much attention as he did formerly; moreover, the colonel is up against the fact that he has finished his Army career without having attained to the rank of general, and the business man is hardly likely to have been a captain of industry if he retired in middle age. So the hypochondriasis secures them attention and serves as an excuse for their not having achieved greater success in life, both of which also help to keep off their feeling of inferiority. The crank "who believes that health is only to be attained by following some special rule of life" holds the same views about health as many of his predecessors of the last century did about religion: both set up a difficult standard to which few are likely to attain; hence the superiority of those that do. The parents that lay down such detailed and devastating rules for their children, whether in the nursery or the preparatory school, are attempting—generally unconsciously—to dominate their children; and the children (probably the same ones, grown up) who will not let father smoke, or mother play bridge, are retaliating by trying to dominate their parents. Does anyone desire to demonstrate his superiority unless he feels doubtful about it?

So all the various hypochondriacs have one thing in common—a sense of inferiority or insecurity—and in so far as we can treat this we can relieve them not only of their symptoms, but of their disease.—I am, etc.,

Wandsworth, March 18th.

F. GRAY.

Hypochondriasis, Labour, and Analgesia

SIR,—Dr. James W. Hamilton's letter in the *Journal* of March 17th (p. 505) represents very well the opinion of some fifty years ago. Our fathers usually maintained that it was most improper for men and boys to be given nitrous oxide for dental extractions. They were more generous to women, however, as they allowed gas for dental extractions, and even chloroform in confinements (very ably administered, too). Dr. Hamilton's "lay scheme to provide anaesthesia in labour" obviously refers to the National Birthday Trust, a body of most able

and disinterested people, with a profound knowledge of their subject. I suggest that he gets in touch with them and really learns what they are doing. As to "chloroform bombs," these dread weapons are 20-minim capsules of chloroform produced by a consulting obstetrician with a long record of distinguished work. Can we not credit this gentleman with some knowledge of his subject?

Dr. Hamilton, I think too, is unduly pessimistic in feeling that we are bent on teaching modern woman that intervention in some form is indispensable in labour, as those of us who have had experience of nitrous oxide analgesia in labour find that instrumental deliveries are less common where this form of analgesia is used than when no relief is given. Let Dr. Hamilton study the work of British women in all branches of industry and science to-day, and then I think he will find that his fears as to the future of the race are unfounded.—I am, etc.,

New Barnet, March 18th.

JOHN ELAM.

SIR,—It is my bounden duty to answer Dr. James W. Hamilton's letter in your issue of March 17th on hypochondriasis. Doubtless someone more qualified to deal with his second point will do so. I am only concerned with his third reason for the opinion that woman is becoming more unfitted to carry through an unaided labour.

England is aware of the advance that has been made by the use of chloroform capsules. For some time I have been engaged—with the aid of a loyal band of assistants—in research work on a new form of analgesia, which has proved successful for the parturient woman. I cannot, therefore, but be impressed that one of two things has happened: either those who hold the opinions of Dr. Hamilton have never seen the relief obtained by the methods of analgesia in midwifery practice such as these, or no pity can exist in their hearts. I would like to pay the highest tribute of gratitude to the National Birthday Trust Fund for its encouragement and assistance to workers in this subject, who, thank God, do not share the views of your correspondent.—I am, etc.,

Liverpool, March 19th.

R. J. MINNITT, M.D.

Acute Thyroiditis following Teeth Extraction

SIR,—I was interested in Dr. Ian Thorburn's case (March 10th, p. 428) because he suggests that the "thyroiditis" was due to infection, and because a month ago I saw a similar case.

My patient was a well-developed young woman of 28, with a swelling of the thyroid, a pulse of 134, and a blood pressure of 168/80. There was a suggestion of exophthalmos. Her illness also began in August, 1933, but after removal of tonsils. In spite of everything she married in the following December (1933). In her case the same cause had been assigned; she had been told that her condition was due to a poison getting into her system from the tonsils, said to have been septic.

I am not going to attempt here a discourse on the aetiology of disease; but why does Dr. Thorburn attribute the "thyroiditis" in his case to infection? He offers no proof that it was so, except that it followed extraction of seven teeth. The cervical lymph glands were unaffected.

Why suppose all disease is due to infection? When I go to the cinema, and by ill luck see a melodrama presented, and my pulse goes up to about 150, is that due to infection? The thyroid enlarges in pregnancy: when

Graves's disease already exists, pregnancy may make it worse. Is this due to infection? Some people may think that pregnancy itself is an infection, since they assign the metabolic aberrations so often occurring in it to what they call "toxins." A man gets pneumonia: marked albuminuria develops; without any ado it is attributed to infection. Judgement is made without considering all the evidence; it is enough to know that on the heels of the "infected" state—a carious tooth, an enlarged tonsil, a pregnant uterus, an inflamed lung—appeared the metabolic aberration.

Is it not time to ask, Whither medicine? Is not the tendency a return towards the superstition of the Middle Ages, with its correlated therapy, as depicted in *Macbeth*, Act IV, Scene i? Surely, we want more efficient brakes. We want even to stop and look round—even to think. Otherwise the word "infection" will lose its connotation. —I am, etc.,

Rugby, March, 10th.

R. H. PARAMORE, F.R.C.S.

Tonsillectomy: Complete or Partial

SIR,—In reply to the question asked by Dr. Freer in his letter in the *Journal* of March 3rd (p. 406), I would like to say that I am in entire agreement with what Dr. T. B. Jobson states in his letter in your issue of March 17th (p. 506).

Diseased tonsils should be completely removed, and in the young up to the age of 8 to 10, and sometimes 12, they can be perfectly enucleated by the guillotine, by the Whillis-Sluder method. It is purely a personal matter whether the one method (guillotine) or the other (dissection) is done, but in experienced hands—and they *must* be experienced—the guillotine method is quicker, and produces less trauma and less shock to these young patients. Convalescence is also shortened. For adults, and for those over 10 to 12 years of age, dissection is the only reliable method.—I am, etc.,

A. MACKENZIE ROSS, M.B.,

Poole, Dorset, March 18th.

Ch.B., D.L.O.

Collective Suggestibility

SIR,—The Occult Committee of the Magic Circle, of which I am chairman, is collecting and analysing the evidence for the rope trick. I need hardly say that this is of the weakest nature. Every claim to have seen it breaks down on investigation. The last resource of a number of these people is that they were hypnotized. My committee would be most grateful if some of your readers, who are experts in hypnotism would give us their assistance. I have endeavoured to read up the subject, and can nowhere find the slightest reason to believe that any man has the power to induce hypnosis in a number of people gathered round him and at some distance from him, without their co-operation and without the opportunity of hypnotizing them individually and by the use of ordinary methods. The contention that the onlookers are so effectively hypnotized that they cannot get up and walk to the edge of the veranda on which they are seated in order to settle simply and easily what has happened to the boy at the top of the rope strikes me as absurd.

It may be said that this is not hypnotization, but suggestion. I find it very difficult to believe that normal, healthy-minded people can, under the influence of suggestion, believe anything so grotesque as that a rope is

thrown into the air and stays there erect, defying the laws of gravity, that a boy climbs it and disappears, etc. It seems much more probable that the people who come forward with such stories have a morbid desire for the limelight. I do not suggest that in all cases they are deliberately uttering falsehoods, though in some cases it is difficult to exclude this possibility. I think that some of them actually believe the stories they tell.

It will not, I think, be hard to trace to their source and lay for good and all the absurd stories about photographs that have been taken without result of any kind. I call them absurd, because I am convinced that the rope trick, as usually described, is never attempted. It is a sheer myth, but I should greatly value the opinion of some of your readers as to this idea of collective hypnotism or collective suggestibility. I am not challenging that a good speaker or a good actor can suggest all sorts of things to an audience, as, for instance, when a conjurer, after throwing up a ball a number of times, palms it, drops it out of the way, and following what would have been its flight with his eye, mystifies his audience as to what has become of the ball. This is a comparatively simple thing to do, but that he could "put across" the same thing with the rope trick appears to me absurd. I think it is a duty incumbent on those who have the knowledge and the experience to show up the flimsy basis on which so many of these so-called scientific experiments rely.—I am, etc.,

London, W.1, March 10th.

R. H. ELLIOT, M.D.,

Lieut.-Colonel, late I.M.S.

Chilblains

SIR,—Dr. Ingram, in the *Journal* of December 23rd, 1933, writes to suggest a treatment for chilblains. He tells us what he considers the cause—namely, sluggish peripheral circulation—and claims that the treatment he suggests is therefore rational. I am not wishing to deny it, but to my mind he is rather like Naaman, who preferred Abana and Pharpar, rivers of Damascus, etc., to the humble Jordan.

I would suggest as my "Jordan" a method of treatment advocated by my teachers in Edinburgh, and one which I have personally found very effective in practice. An elastic band, half an inch or so in width, is applied round each wrist sufficiently tightly to cause just enough venous congestion to render the hands faintly blue. This is left on for ten to fifteen minutes. When removed the hands should be held above the head for a minute or two till the colour returns to normal. (For practical purposes a convenient routine to suggest to the patient is to apply the bands on rising from bed and wear them till he, or she, has finished dressing.) This is done daily for several weeks, and in addition to being most effective in preventing trouble in the susceptible, is also remarkably efficient in those with established lesions and even cracked, chapped hands as well.

My most successful case was an elderly gentleman of over 70, who had had much trouble with his hands every winter for years. He had tried much medication, including calcium. He employed the above treatment as soon as the cold weather began, and throughout the winter had not even a suspicion of a chilblain. It would seem to me that this method is just as rational as the thyroid medication advocated by Dr. Ingram, and has this advantage, in addition, that it is less expensive.—I am, etc.,

GORDON C. GILLISON, M.B., Ch.B.

Hankow, China, January 26th.

EPSOM COLLEGE ELECTIONS

At their meetings in February last the Conjoint Committee and the Council of Epsom College Royal Medical Foundation elected the following to pensions as from April 1st, 1934:

Dr. Hugh Alston, Dr. John Good, Mrs. Sophia Blott, and Mrs. May Walker, Ordinary and "Dr. Strong" pensions of £40 a year.

Dr. Asher Lyons Altman, a "France" pension of £42 a year.

Miss Margaret A. C. Keene, a "Cheyne" annuity of £40 a year.

Miss Margaret A. R. Goodinge, a "Henry Duncalfe" annuity of £30 a year.

Miss Maud Dawson, an "S. H. Tait" annuity of £16 16s. a year.

Miss Lydia M. Braidwood and Mrs. Eunice C. Nelson, the senior pensioners on the list, were each awarded an extra "Da Silva" pension of £20 a year.

Isabel Shoolbred Rowat was awarded a "St. Anne's" scholarship of £120 a year.

Obituary

SIR WILLIAM NORMAN, K.C.B., F.R.C.S.Ed.

Surgeon Vice-Admiral and formerly Director-General of the Medical Department R.N.

We regret to announce the death, on March 16th, of Surgeon Vice-Admiral Sir William Norman, who was Medical Director-General R.N. during the last eighteen months of the war.

William Henry Norman, son of Fleet Paymaster W. H. Norman, R.N., was born on December 13th, 1855, and, after school days at Plymouth, studied medicine at King's College Hospital, London. He obtained the diploma of M.R.C.S.Eng. in 1878, and the L.R.C.P.Ed. three years later. Following the family tradition he entered the Royal Navy in 1882, joining up at Haslar as a surgeon. At the end of ten years' service, mainly afloat, during which he was mentioned in dispatches for "skilful surgery in trying circumstances" in an action with a slave dhow off Zanzibar, he was promoted to the rank of staff surgeon. In 1895 he served with the Naval Brigade under Admiral Rawson, and after returning home was appointed to H.M.S. *Boscawen*, the training ship for boys at Portland. In 1908 he was promoted deputy inspector-general, and in 1913 surgeon general. Throughout the first three years of the war he was at Plymouth in medical charge of the naval hospital. In June, 1917, he was appointed Director-General of the Medical Department at the Admiralty, with the rank of surgeon vice-admiral, and held this post for two years, when he retired from service on attaining the age of 65, and went to live near Launceston in Cornwall.

Sir William Norman received many well-deserved honours. He was created C.B. in 1916, and K.C.B. two years later, and was appointed an honorary surgeon to the King in 1920. His foreign decorations included the Grand Cordon of the Sacred Treasure of Japan, Commandership of the Legion of Honour, of the Grand Order of Belgium, and of the Star of Rumania, and the distinguished service medal of the United States. He was a Knight of the Order of St. John of Jerusalem, and a Fellow of King's College, London. The Royal College of Surgeons of Edinburgh elected him an honorary Fellow in 1919, and in the same year he received the honorary freedom of the Apothecaries' Society of London.

Sir HUMPHRY ROLLESTON, Bart., who was temporary surgeon rear-admiral during the war, sends the following tribute:

Many, and perhaps in a special degree those who were temporary surgeons in the Royal Navy during the war, will hear with very deep regret of the death of Surgeon Vice-Admiral Sir William Norman, who was Medical

Director-General during the eventful years June 1st, 1917, to June 1st, 1919. After a painful fight for life, prolonged for two months, with more than one abdominal operation, he died in the Royal Naval Hospital, Plymouth, which he had so successfully and happily managed as surgeon general from 1913 to 1917. It is difficult to imagine that he ever made an enemy; he certainly had innumerable friends, and to meet him was a tonic like the fresh air of a sunny day in spring. A fine figure of a man with the healthy complexion and all the qualities of a genuine sportsman; he loved the country more than official power, thoroughly enjoyed the retirement, far in the heart of Cornwall, he so well deserved, and leaves behind him pleasant and affectionate memories.

SIDNEY REGINALD DYER, M.D.

Late Commissioner of Prisons for England and Wales

The death of Dr. Sidney Reginald Dyer, in his seventy-fourth year, occurred on March 14th, after a short illness. The son of the late Joseph Dyer of Chiswick, he was educated privately and at the Middlesex Hospital. He qualified M.R.C.S.Eng. and L.S.A. in 1883, and became a Licentiate of the Royal College of Physicians in 1884. He obtained the M.D.Brussels degree with honours in 1888, and the D.P.H. of the English Conjoint Board in 1891. He was called to the Bar at the Middle Temple in 1896. At the Middlesex Hospital he served as house-physician to Dr. W. Cayley, and after a house-surgeoncy at the County Hospital, Huntingdon, joined the Prison Medical Service in 1885. He served at Wandsworth, Stafford, Dartmoor, and Brixton Prisons, and in 1917 was appointed Medical Inspector of H.M. Prisons, England and Wales. In 1921 he was further promoted, and became a Commissioner of Prisons and Director of Convict Prisons, and retired in 1923. During the war he acted as Home Office medical referee to the German internment camps. He was a member of the Medico-Legal Society, and served on the council of the Central Association for Mental Welfare. He was also a member, and at one time vice-president, of the Devonshire Archaeological Society, and held a commission as captain in the 1st London Volunteers, Royal Engineers. On retirement he sat for many years as a justice of the peace for the county of Somerset.

Throughout his career Dyer set an example of single-minded devotion to duty to all those who had the privilege of working with him, and was a particularly loyal, unselfish, and generous colleague. During the years 1909-17, as senior medical officer of Brixton Prison, he was constantly in attendance in the criminal courts in London and the adjacent counties, and the judicial authorities and members of the Bar soon learnt to appreciate the value of his opinion and the unbiased manner in which his evidence was presented. His sympathy, humane understanding of the frivolities and passions of others, and kindness of thought were accountable for much of the success he achieved as an examiner into the mental condition of prisoners awaiting trial. His equanimity and sincerity stood him in good stead when under prolonged examination in the witness-box. It is probably true to say that the years at Brixton Prison, although exacting and often harassing, were particularly satisfactory to Dyer, for the preparation of his cases for the criminal courts and attendance at the courts appealed strongly to both his medical, and his legal training. A man of such wide sympathy might easily have become disheartened and depressed at the tragedies which daily passed before him, had he not possessed a strong sense of humour. As medical inspector his visits to the various prisons were always welcomed by the medical staffs, who looked upon him as a personal friend as well as an official adviser. His talents and wide knowledge were given full scope when

he became a Prison Commissioner, and his decision to retire, in 1923, was accepted with great regret by his colleagues.

Dr. Dyer was for many years a member of the British Medical Association, and served on the Representative Body at the Annual Meeting at Exeter in 1907. He married in 1898 Rose, daughter of Captain Talbot Price, R.N., and leaves one son.

THE LATE DR. A. A. MONTAGUE

We have received from Suva some further appreciations of the work and character of Dr. Aubrey Montague, late chief medical officer, Colony of Fiji, of whom an obituary notice appeared on February 10th.

Dr. T. CLUNIE, honorary secretary of the Fiji Branch of the B.M.A., writes:

Dr. Montague had great experience in the colony, and his advice was often sought in matters quite outside his department. He rendered

valuable service in connexion with education and other matters, and attended the Imperial Conference in 1926. Two institutions which benefited by his great experience, his keen insight, and administrative ability were the Central Medical School and the Makogai Leper Asylum. The Native Medical School of Fiji had come into being about 1885, but its pupils were native Fijians, and its activities were limited to the Colony of Fiji. The

activities of both the medical school and the leper asylum were greatly extended during Dr. Montague's tenure of office. To-day natives from all the Pacific groups may attend the Central Medical School, while the Leper Asylum receives patients from most of the groups and from New Zealand. As chief medical officer, Dr. Montague was consulting physician and surgeon to the Colonial War Memorial Hospital. He was a practised surgeon and an able clinician. Of a quiet and retiring disposition, yet possessing great charm, he was indeed "The Beloved Physician." He had been a good tennis player, and latterly was a keen golfer. In social life he is perhaps remembered best as a good bridge player, who never lost his charm, and as a very able after-dinner speaker. The late C. E. Montague, novelist, and once of the *Manchester Guardian*, was a brother. A surviving brother, Frank Montague, is an Oxford don.

Dr. S. M. LAMBERT, Director in the South Pacific, Rockefeller Foundation, writes:

One of the greatest influences on my life was my intimate association with Dr. Montague through the period of his chief medical officership in Fiji. I never knew him to do an underhand thing during that time or ever go back on his word, not alone in his dealing with me, but in his conduct of his office, of which I knew a great deal. He was one of the three ablest men I have known in the South Pacific in the last fifteen years, and not the third by any means. The impression he left with one whom this shy man considered worthy of a closer intimacy was one of great intellectuality well controlled. He was a man of high culture, but well balanced, with good practical judgement. Dr. Montague's leadership was responsible for the Central Medical School in Suva, Fiji, in which eight South Pacific groups co-operate to train natives in simple medicine to care for their own people; he was responsible for the enlargement of Makogai

Leper Hospital in Fiji; so that South Pacific groups co-operate there in the care of their lepers, and this institution was brought, under his care, to a high point of perfection. His administration of his office was most economical, and each pound of Government money was spent with scrupulous care, though it was not parsimony, as during his term the medical department had its largest expansion, especially along lines of preventive medicine. His protection of Government funds was refreshing in these days. On matters outside of his department his advice was often sought and taken by Government on account of his sagacity and clear view-point; and it was a great shock to me when this man, who had given thirty years of outstanding loyal service to the Empire, was allowed to retire without suitable honours, which he had so richly deserved. His work had been done so unobtrusively, and he was so lacking in self-seeking, that only when he retired was the great gap caused by his absence realized. I shall never see his like again.

Universities and Colleges

UNIVERSITY OF LONDON

At a meeting of the Senate on February 21st it was resolved to institute, in accordance with the regulations on University Titles (*Calendar*, 1933-4, pp. 235-46), a University Readership in Bacteriology tenable at St. Bartholomew's Hospital Medical College, and a University Readership in Morbid Anatomy tenable at University College Hospital Medical School.

The regulations for the M.B., B.S. Examination for Internal Students (*Red Book*, 1933-4, p. 219) were amended by the transference of the last sentence of the fourth paragraph under the heading "Details of Examination" to the end of the fifth paragraph, and by the substitution therefor in the fourth paragraph of the following:

"Registered medical practitioners who pass in one group only of the M.B., B.S. Examination will be eligible to enter for the other group at any time on payment of the proper fee."

The regulations relating to the Third Examination for Medical Degrees (*Blue Book*, September, 1933, p. 265) were amended (a) by the transference of the last sentence of the third paragraph under the heading "Details of Examination" to the end of the fourth paragraph; and (b) by the addition of the following sentence to the end of the third paragraph:

"Registered medical practitioners who pass in one group only of the M.B., B.S. Examination will be eligible for the other group at any time on payment of the proper fee."

Dr. R. A. Young has been appointed representative of the University at the Twentieth Annual Conference of the National Association for the Prevention of Tuberculosis in London in June.

A Carpenter Medal, together with a money prize of the value of £20 in all, will be awarded by the Senate in 1934 for work of exceptional distinction in statistical, genetic, comparative, or experimental psychology, including the functions of the central nervous system and special senses, for which a doctor's degree (other than the Ph.D. Degree) has been awarded during the period of three years ending on May 31st. No award will be made, however, unless in the opinion of the Senate work of sufficient merit has been presented. Candidates, who may be either internal or external students, must forward their applications not later than June 10th to the Academic Registrar, from whom further particulars may be obtained.

Studentships

The Geoffrey E. Duveen Travelling Studentship in oto-rhino-laryngology, of the value of £450, will be awarded annually. The tenure shall, in the first instance, be for one year, part of which will be spent in study abroad, in accordance with a scheme approved by the Geoffrey E. Duveen Studentship Board, but it may be extended for one or two years, and during the extended period the student may be allowed to undertake research at the Royal Ear Hospital, or some other laboratory approved for the purpose. Grants for promotion of research in oto-rhino-laryngology, or in any part thereof, may also be made by the Trust Fund. Full particulars can be obtained from the Academic Registrar, South Kensington, S.W.7, and prescribed forms of application must reach him not later than June 11th, together with a statement of the nature of the research proposed and a scheme of study for the approval of the Board.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons will rise for Easter on March 29th and resume on April 9th. The Budget will be introduced on April 17th. This week the House of Commons discussed Scottish Bills, the co-ordination of the Defence Services, and unemployment in the distressed areas.

Import orders were approved. Additional Import Duties (No. 8) Orders, laid on the table of the House of Commons on March 19th, provide for the removal of the additional duty on dried foliage, dried flowers, and the like of the kinds used solely for the manufacture of drugs or medicine.

The India Pay (Temporary Abatements) Bill, the Mining Industry (Welfare Fund) Bill, and the Rural Water Supplies Bill were read a first time in the House of Lords on March 14th. On the same date the Lords read the Wirral Joint Hospital District Bill a second time. The Dyestuffs Importation Bill was read a second time by the Lords on March 13th. On March 20th the Rural Water Supplies Bill was read a second time.

Mr. Oliver Stanley, the Minister of Transport, received a deputation on March 20th, which came to advocate statutory compensation to hospitals' and medical practitioners for aid given after road accidents. The deputation, which had been appointed by a meeting called by the Parliamentary Medical Committee, was introduced by Sir Francis Fremantle and consisted of the Earl of Iveagh, the Earl of Kinnoull, Lord Luke, Lord Moynihan, Sir Arnold Wilson, Colonel T. C. R. Moore, and Dr. A. B. Howitt. The speaker emphasized the urgent need for compensation for services rendered and for material loss resulting from the treatment of road accident cases. The deputation suggested that in the forthcoming Bill to deal with road accidents there should be incorporated provisions on the lines of the Road Traffic (Emergency Treatment) Bill, which had passed through all its stages in the House of Lords. The Minister, in reply, expressed his sympathy for the position of hospitals and medical practitioners in connexion with road accidents, and promised to give careful consideration to the views put forward by the deputation. The Government Bill on the subject is to be introduced before Easter.

Defence Medical Services

B.M.A. and Schemes for Recruitment

In the House of Commons, on March 15th, Mr. DUFF COOPER made the annual statement on the Army Estimates.

Sir FRANCIS FREMANTLE dealt with the Medical Services. He said the report of the investigation into the Medical Branches of three Fighting Services by a committee, of which Sir Warren Fisher was chairman, had been issued last summer. On the Army Medical Services that committee reached a conclusion which in general was accepted by the medical profession, including the British Medical Association. This concerned the continued lack of recruits for the Medical Services, and how to meet the competition of civil life when appealing to young qualified medical men of about 26. The material prospects of the Services hitherto had been good enough for the young man, but burdensome when he married and had a family, and still more so when he retired. The committee suggested improvement in meeting the desire of men to devote themselves to the profession, and said it was possible, by adjustment and upgrading, to give better prospects to individuals, who could obtain promotion earlier, continue longer in the Services, and make a career. On the other hand, there should be a short service, so that those who entered for five years might retire, with a grant of £1,000, to civil life and practice. This would give a great opportunity of getting sufficient recruits for the Services. The House had not yet the decision of the Government on the project. The British Medical Association received the other day the reply that the Army Council found it necessary

to discuss the recommendations of the Fisher Committee with the India Office, which had to communicate with the Government of India. Could Mr. Duff Cooper indicate when these matters would be dealt with? Meanwhile, the difficulty remained, and could not be treated lightly. In the fifteen years after the war the Army had gone on with a diminishing number of recruits for medical officers, and with a number of elderly officers assisted by civilians, who would not be able to proceed to the higher ranks. The whole Service was disorganized, and the Army was heading for disaster, such as resulted at the beginning of the South African War, from the deliberate starvation of the Medical Services by the War Office and the indifference of Parliament. Not only the Medical Services, but the British Dental Association was concerned. That Association had a definite scheme. He hoped the War Office would get a scheme of recruitment for the men who were wanted in the Medical Services.

In reply, Mr. DUFF COOPER said he hoped the Warren Fisher Report would be adopted, and that the difficulties with regard to the Indian position would not prove insuperable. The report dealt with three Services, all of which were anxious it should be adopted. Only from the point of view of the Army in India was it being held up.

The House then went into committee and carried the Army Estimates for men, pay, half-pay, pensions, and other charges. The strength of the Army in 1934-5 was authorized at 149,500, all ranks.

Housing Progress

Replying to Sir A. Sinclair, on March 14th, Sir GODFREY COLLINS said the numbers of State-assisted houses under construction by local authorities and private enterprise in Scotland at the end of last October, November, December, and January were 20,238, 19,259, 18,856, and 18,694 respectively. The numbers of houses approved for subsidy but not begun at the same dates were 5,008, 4,794, 4,609, and 3,441 respectively. Only one guarantee scheme under Section 3 of the Housing (Financial Provisions) (Scotland) Act, 1933, had been submitted, and this was now under consideration.

Sir HILTON YOUNG stated, on March 14th, that the housing measure announced in the King's Speech would include provisions for combating the evils of overcrowding. Assistance from public funds would be available for this purpose subject to certain conditions. In addition there would be provisions dealing with reconditioning.

In reply to Mr. Chorlton, on March 15th, the Minister said that the Manchester Town Council had not yet submitted to him any order in connexion with the Collyhurst slum-clearance area. Until that had been done the date of the inquiry could not be fixed.

Contraceptives Bill

In the House of Lords on March 20th Lord DAWSON OF PENN moved the third reading of the Contraceptives Bill. He said that he wished to make clear that the measure did not interfere with the sale of contraceptives in any shop to any person of any age. It did not prevent them being exhibited in shop windows, nor did it prevent notices being put up that such sale took place within. What the Bill did was to control the public exhibition of drawings and diagrams, and the sale of contraceptives in streets and other public places by means of hawking and automatic machines. Lord Dawson once more expressed his conviction that the best way to exorcise evil was to promote good, and that the best way of dealing with contraception was to remove the atmosphere of falsity surrounding it. If a ballot were taken of married people under the age of 40 throughout the country he thought that three-quarters or seven-eighths of them would desire to be in a position to regulate the numbers and spacing of their families. How otherwise could they explain the steady fall in the birth rate and the increasing intervals between children? Contraceptives were used by all classes. There was a feeling, however, that the knowledge available to the rich was being withheld from the poor. He appealed to the Ministry of Health to permit a wider discretion to local authorities, so that birth control instruction might be given to married women. That would direct the sale into regular channels, and save newly married women medically unfit for pregnancy from endangering their lives. After the

generous reception which their lordships had given to this Bill he hoped that the Government would look benevolently on the measure. The Bishop of London said that the Bill was a very restricted measure, and he had received evidence that day which showed some of the mischief which it was designed to prevent. Three shops had been investigated. One shop in London was mainly patronized by unmarried men. Another shop in a Midland town had a slot machine outside, from which contraceptives were sold for a shilling, and even for sixpence. In a barber's shop in a little country town contraceptives were displayed in the windows. These facts showed that those who thoroughly disapproved of contraceptives could vote for this Bill, just as Lord Dawson and his friends could also vote for it. He (the Bishop) hoped the Government would see its way to assist the passage of the Bill. The Bill was read the third time and passed.

Conditions in Offices

In the House of Commons, on March 16th, Mr. THORNE moved the second reading of the Offices Regulation Bill. He said similar Bills had been introduced in 1926 and 1928. He spoke of the number of offices, even Government ones, where employees worked underground in places badly lit and badly ventilated. The Bill provided that offices, and rooms used as such, must be whitewashed once in fourteen months. It laid down that 500 cubic feet must be allowed for every person working in a room, or if the room was used night and day, at least 1,000 feet. Cubic space provision did not apply to a room more than 12 feet high. Clause 9 of the Bill laid down that no person under 16 should work in any office. Mr. LEONARD, in seconding the Bill, pointed out that the Shops Bill, introduced lately in the House of Lords by the Government, would protect clerical workers who worked in association with retail trades.

Mr. HERBERT WILLIAMS moved the rejection of the Bill. He admitted that many offices ought to be improved. Those of London, in general, were much better than those of some provincial towns. In a great deal of the building recently done the standard had been raised enormously. Section 91 of the Public Health Act gave power to deal with premises which were a nuisance or injurious to health, and also with "any house or part of a house so overcrowded as to be dangerous or injurious to the health of the inmates." His impression was that an office was a "house," and would also come under the term "work place" in the same Act. The bulk of the declaratory parts of Clause 1, Subsection 1, of the Bill were covered by existing legislation, though the provisions about the lighting and water supply of offices were not. The standard laid down in the Bill for cubic air space per person was more ample than that observed in the House of Commons. The Public Health Act of 1890 anticipated another of the proposals in the Bill by securing that every building where persons were employed in a trade or business should be provided with sufficient and suitable sanitary conveniences. Mr. LEVY seconded the rejection of the Bill. The existing Public Health Acts, he said, gave full power to local authorities to deal with premises injurious to health. Mr. RHYS DAVIES surmised that about 1,000,000 persons were employed as clerks in the United Kingdom. Even when local authorities adopted the health provisions of the 1875 and 1890 Acts medical officers of health universally declared they had not sufficient powers now to deal with unhealthy offices, shops, and workshops.

Mr. DOUGLAS HACKING, for the Home Office, said the Bill did not content itself with matters within the scope of the Public Health Acts—sanitation and ventilation. It dealt also with overcrowding, rest-rooms, restriction of periods of employment, periodical returns of persons employed, doors being made to open from the inside, safety apparatus, and other matters, which could only be dealt with properly by the Home Secretary. The Bill was a restrictive measure, and Mr. H. G. Williams's criticism of it, though harsh, was fair. Mr. Rhys Davies was wrong in saying that the Health Acts were not compulsory. The Act of 1875 was compulsory, and under it the local authority was compelled to take notice of a nuisance. There was no doubt that the words "premises" and "house" in that Act included offices. The official view was that "work place" in that Act did extend to offices. Some local authorities did not accept that statement, and no test case had ever been

brought. In the report for 1928 of the Chief Medical Officer of the Minister of Health, Sir George Newman said that most of the medical officers of health consulted doubted whether systematic inspection was necessary. Sir George drew attention to the need of special consideration being given to basements, but reported no evidence of abuses which would justify the present Bill. The Bill disregarded the recommendations of the Select Committee on Shop Assistants which reported in 1931, and of which Mr. Rhys Davies was a member. The proposal in the Bill about air space was far in excess of anything found in factory legislation. So were the prohibitions on the employment of young persons. He assured the House that the Government had sympathy with the intentions of Mr. Thorne, and this had been borne out by the Shops Bill. Mr. Hacking submitted that local authorities had to-day adequate powers to undertake systematic inspection of offices.

Sir FRANCIS FREMANTLE said that for eight years he had brought to the notice of successive Ministers of Health the need for legislative or administrative action in regard to the evils the Bill sought to remedy. There was reason for disquiet about the health of those who worked in some offices. He had gone very thoroughly into the matter with the life tables in the census of 1921. Clerks at some ages showed a worse mortality, both for phthisis and general mortality, than the figures for all occupied and retired males. In the higher ages, from 35, the mortality of clerks, both phthisis and general mortality, was considerably better than that for all occupied and retired males. The figures for clerks of banks, insurance offices, and railways were better than for all occupied and retired men, those for commercial clerks were considerably worse. In good offices health was as good as anywhere else. It might be very bad in old factories and workshops which had clerical offices fitted in somehow. A basement could be healthy, but it had to be made so by attention to ventilation, lighting, and so on.

Mr. HICKS said that the Trades Union Congress, the Clerks' Association, and the Women Clerks' and Professional Workers' Association were not satisfied that the grievances they suffered could be adequately dealt with under the present laws.

Dr. O'DONOVAN said that office workers were exposed to strain on health no less than factory workers. The work done in the modern factory in health records, welfare work, health supervision, prevention of accidents, and following-up of absentees was an astonishing piece of preventive medicine in which the Home Office, the trades unions, and the employees co-operated. Yet in London these lessons in hygiene were neither remembered nor put into practice. In London many insanitary small houses were now offices. The medical care of office workers was the next line along which public health measures should be developed. Nothing but good to the public health would follow if the system of "appointed factory surgeons" could be introduced within the offices of the country. All the preventive work of the Bill could be carried on with little inspection. The possibility of a surprise visit would keep a neighbourhood in good order for months on end. He welcomed the Bill as an attempt to check the ill effects of the over-urbanization of life.

Mr. ARTHUR GREENWOOD said every local authority knew the powers under the Public Health Act of 1875 were utterly inadequate. Any body of medical officers of health knew this was true. The death rate among clerks was almost double that in agriculture.

Mr. THORNE moved the closure. This was rejected by 60 to 40, and the question that the Bill be read a second time was not put.

Silicosis.—On March 13th Mr. E. BROWN, replying to Mr. E. Williams, said that the problems of the causation and diagnosis of silicosis were being investigated under the direction of the Industrial Pulmonary Diseases Committee of the Medical Research Council and in other quarters. This he believed to be the best method of attacking the problem of this disease, and at the present stage of the investigations he did not think that to set up a committee to inquire into the effect of stone dusting as a contributory cause of silicosis, as suggested by Mr. Williams, would serve any useful purpose. At a later stage, however, he would take the suggestion of the hon. member into consideration. Mr. T. SMITH asked whether there was any evidence of stone dusting being a contributory

cause of silicosis, and whether it was regarded as such. Mr. E. BROWN: Not that I know of. Mr. TURTON asked if it would not be simpler to make silicosis an industrial disease under the Workmen's Compensation Act. Mr. BROWN: No; there are many other causes involved.

Health of Elementary School Children.—On March 13th, in reply to Sir W. Jenkins, Mr. RAMSBOTHAM said that the percentages of children in public elementary schools in England and Wales found on routine medical inspection to require treatment (excluding cases of uncleanliness or dental disease) at the age of 5 or at entry to school were: 22.3 in 1925; 19.8 in 1930, and 18 in 1932. The percentages at the age of 8 were: in 1925, 26.1; in 1930, 22.5; and 1932, 20.3. At the age of 12 the percentages were: in 1925, 24; in 1930, 20.7; and 1932, 18.3. In further reply to Sir W. Jenkins, Mr. Ramsbotham said that there were at present fifty-eight nursery schools recognized by the Board of Education. All those schools were in England. Children might be admitted at the age of 2, and usually left at the age of 5. The children were submitted to periodical medical examination, and the defects discovered were similar to those found in children attending public elementary schools. No information was available as to the percentage of children suffering from defects on leaving these particular schools. They were all subject to the usual examination on entering the ordinary public elementary schools.

Boiler Scalers in Docks.—Sir J. GILMOUR, replying on March 13th to Dr. O'Donovan, who asked if he would take steps to obtain power to supervise the health and working conditions of boiler scalers in docks as he did for those in factories, said that that point had been noted for legislation when opportunity arose, but he saw no prospect of this during the present session. He understood that conditions had improved during the last few years, and he would consider what more could be done without legislation.

Health Publications by Local Authorities.—Replying, on March 13th, to Mr. Groves, who asked if the Minister had authorized the distribution by the Ipswich Public Health Committee of a pamphlet in favour of vaccination, Sir HILTON YOUNG said that any local authority might arrange for the publication in its area of information relating to health or disease, and might defray the whole or part of the expenses incurred. His approval was not required. He was informed that the cost to the Ipswich rates of distributing a pamphlet on vaccination through the vaccination officers was approximately 36s. per annum.

Medical News

A course of post-graduate lectures on urology will be given at St. Paul's Hospital, Endell Street, W.C., on Wednesdays, at 4.30 p.m., from April 18th to May 30th. The course is free to registered medical practitioners and students.

An intensive course in laryngology, rhinology, and otology will be held at the Central London Throat, Nose and Ear Hospital, Gray's Inn Road, W.C.1, from April 16th to May 12th. The course, which is especially suitable for D.L.O. students, will include an anatomy and physiology, and operative surgery classes, a practical course in peroral endoscopy, and a course in pathology and bacteriology.

The Fellowship of Medicine announces a further lecture-demonstration, on purpura, by Dr. Clark-Kennedy, at 11, Chandos Street, on March 27th, at 2.30 p.m. There will be no lecture-demonstration on April 3rd. An all-day course in proctology will be given at St. Mark's Hospital from April 9th to 14th. An afternoon course in infants' diseases will be given at the Infants Hospital from April 9th to 21st, and a course in rheumatism, on Tuesdays and Thursdays, at 8.30 p.m., at the British Red Cross Clinic, from April 10th to 26th. The Southend General Hospital has arranged a week-end course in general medicine and surgery on April 14th and 15th. Six lectures, on the diagnosis and treatment of chronic diseases of the chest in general practice, will be given by Dr. P. Ellman, at 11, Chandos Street, on Wednesdays and Fridays, at

8.30 p.m., from April 11th to 27th. Demonstrations for candidates for the M.R.C.P. have been arranged during April, and particulars may be had from the secretary of the Fellowship, 1, Wimpole Street, W.1.

An international congress on lymphatism will be held at La Bourboule on June 9th and 10th. The papers and discussions will relate to the aetiology and pathogenesis, forms and varieties, diagnosis, and treatment of this condition. Among those taking an active part in the proceedings will be Professors Marfan, Nobécourt, Lereboullet, Cruchet, and Giraud, of France; Professors Martínez-Vargas and Suner of Spain; Professors Tailens of Switzerland, Gorter of Holland, Moro of Germany, and Comba of Italy; and Dr. Alan Moncrieff from Great Britain. In connexion with this congress there will be a banquet on June 9th, a special excursion on June 10th, and various motor car drives on June 11th. The subscription for membership is 100 francs. Further information may be obtained from Dr. H. Diffre, Federation of the Health Resorts of France, Tavistock House North, Tavistock Square, W.C.1.

The sixth Congress of the International Union of Midwives will be held from May 25th to 29th at the Midwives' Institute, 57, Lower Belgrave Street, S.W.1. The subject for consideration is the training and education of midwives. Particulars may be had from the International Congress Secretary at the above address.

The nineteenth Congress of French Speaking Medical Jurists will be held at Lille, from May 27th to 30th, under the presidency of Professor J. Leclercq of Lille, when the following papers will be read: "Blood Groups in Legal Medicine and Anthropology," introduced by Dr. Lattes of Italy, and R. Dujarric de la Rivière and N. Kossovitch of Paris; "Painful Sequelae of Trauma and their Indemnification," by Héger-Gilbert and De Laet of Brussels; and "Contradictory Mental Expert Evidence," by Raviart and Vullier of Lille. Further information can be obtained from Dr. Müller, 14, Rue de Friedland, Lille.

The first International Congress of Endocrinology will be held at Marienbad from May 24th to 26th, under the presidency of Professor Julius Bauer of Vienna. The subjects for discussion, among others, will be hormones and vitamins, association of hormones, endocrine regulation of growth, carbohydrate metabolism, myxoedema, hyperthyroidism, and treatment of endocrine disturbances. Further information can be obtained from Professor Bauer, Mariannengasse 15, Wien IX.

A series of cinematograph films showing the technique of certain major abdominal operations is being prepared at the Royal Waterloo Hospital in Waterloo Road, London. The films are intended for use in the post-graduate teaching of surgery and for instructional purposes in general. The operations are being performed by surgeons attached to the hospital, and complete cinematographic records have already been obtained showing the removal of a stomach for cancer and of a spleen for uncontrollable bleeding in a child.

Dr. Luke Gerald Dillon, O.B.E., J.P., has retired after practising for fifty years in Seaham, where he had held the appointments of medical officer of health, physician to the Seaham Harbour Fever Hospital, and medical officer to the railway and post office. During the war he was in charge of the Seaham Hall Auxiliary Hospital. He was presented last month by the local urban district council with an inscribed silver cigarette case in commemoration of his forty years of connexion with it as medical officer of health and by the officers of the council with a gold-mounted walking-stick.

All antivaccination societies in Prussia have recently been dissolved by an order of the Minister of the Interior, who has also forbidden any public antivaccination demonstrations.

A severe epidemic of influenza has recently occurred at Tokyo, where 30 per cent. of the population has been attacked and 150 deaths have occurred daily.

Dr. Karel Friedrich Wenckebach, formerly professor of medicine at Vienna, has recently celebrated his 70th birthday.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBER** of the British Medical Association and the *British Medical Journal* is **EUSTON 2111** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Antology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, Medicisera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

The Pox Doctor's Clerk

Dr. PHILIP GOSSE (Steyning) writes: The other day a friend of mine was out hunting, and four foxes were found in the small withy-bed, when a farm labourer exclaimed to the master: "As lucky as the pox doctor's clerk." Can any medical historian explain this surprising saying? What is a pox doctor, why had he a clerk, and why was he lucky?

Callosities

Dr. J. M. CRAIG (High Wycombe) writes: In reply to "Perplexed" (March 17th, p. 515), I would suggest that he tries a "Jones" bar nailed obliquely across the boot or shoe behind the heads of the great and little metatarsals. This will relieve the pressure on the callosities. The callosities can be softened by putting on a patch of elastoplast strapping. In my experience these callosities are prone to occur in elderly diabetics. This bar of leather should be one-half to three-quarters of an inch deep on the inside to one-quarter to one-eighth deep on the outside, and about three to four inches broad.

Income Tax

Salary—"Economy Cuts"

"C. T.," whilst employed by the L.C.C., received a salary which was subject to "economy cuts." Is he liable on the nominal salary or the net amount received?

* * On the net amount only.

LETTERS, NOTES, ETC.

Greenstick Fracture at Age 27

Dr. LEONARD BARRIER (Bristol Mental Hospital, Fishponds) writes: The following case may be of interest in view of the fact that Dr. R. Salisbury Woods has reported a similar case in a male, aged 21, in your issue of March 3rd. A man, aged 27 years 10 months, while playing Association football in October last, fell on his hand with his arm extended. He complained of severe pain in his forearm and acute tenderness over the centre of the radius. He was unable to pronate or supinate his hand without a good deal of pain, and he had little or no grip. The forearm was considerably swollen and tense. In the absence of any evidence of a fracture a diagnosis of strained flexor tendons of the forearm was made. The condition was treated with lotio plumbi & opio, firm bandaging, and massage at frequent intervals. The swelling quickly subsided and the pain became less acute, but pronation and supination of the hand was still painful and the grip weak. Three weeks after this accident the patient had the misfortune to have his injured arm jammed against a doorpost, the force of the blow being applied immediately over the site of the

previous injury. Again there was no deformity or any symptoms to suggest a fracture, but it was deemed advisable to have an x-ray examination of his arm. The skiagram showed a greenstick fracture of the radius situated about the middle of the bone. There was a definite crack in the anterior surface of the radius extending about half-way through the bone, and here the bone had split longitudinally to the extent of a little over a quarter of an inch on either side of the base of the crack.

Jubilee of the word "Tabloid"

March 14th was the fiftieth anniversary of the registration of "Tabloid" as a trade mark. "Tabloid" is a coined word, registered in 1884 by Burroughs Wellcome and Co., successors to Brockedon, who originated compressed medicaments in the form of biconvex disks under the designation of "compressed pills." Thirty lines are devoted to it in the *Oxford English Dictionary*. The ease with which the word "tabloid" comes to the tongue and the universal recognition of the high standard of quality of all products issued under this trade-mark has entailed a very diligent guardianship of the owners' rights. Until 1903 the owners' exclusive right to the word remained unchallenged, but in that year a successful action against "passing off" was brought in the High Court of Justice. "Tabloid," as a result of these proceedings, was certified under Section 77a of the Trade Marks Act, 1883-8, and Burroughs Wellcome and Co. were awarded damages and costs. Time and again since then injunctions against infringement have been granted in courts of justice both in the British Empire and in the United States of America. Even a foreign pharmacopoeia has been required to publish a correction in regard to misuse of the word in the text.

Definition of Terms

"M.B.Oxon" writes: In the *British Medical Journal* of March 10th (p. 454), and in the previous week's issue (p. 401), various writers express conflicting views on menstruation and ovulation not always in very decorous language. At the present time, when so much is written not only in professional papers but in the lay press about birth control, it is very confusing to find that there seems to be no very great certainty about even the meaning of such technical terms as "menstruation." It would be helpful if someone who can speak with authority on the subject were to summarize the present position, distinguishing what is generally admitted from what is speculative. As things are, many medical men must feel that the ground is slipping from under their feet.

How to Expedite Settlement

A correspondent in South India sends us a copy of a letter from an Indian doctor to the son of one of his patients. "I came across it," he says, "during some official correspondence and took a copy, as I thought it might be of interest to your readers." The letter runs as follows:

Dear Mr. —

Herewith I enclose, as per your desire, my bill for having so far attended on your dear mother. She has passed through a very great crisis, and, at such an advanced age as hers, it is only by God's grace that she has been spared to us. Praying that she may enjoy a long lease of life,

I remain, yours sincerely,

P.S.—I request that you will expedite the settlement of the bill as much as possible.

Increased Intraocular Tension as a Cause of Severe Frontal Headache

A Correction

In a letter referring to his article on this subject, in the *Journal* of January 20th, Flight Lieutenant R. L. Raymond points out that on page 103, col. 2, line 8, the sentence, beginning "In this case . . ." should read: "In this case note the previous unavailing course of salines and A.P.C., and the complete withholding of A.P.C. while in hospital." The point is emphasized that in Case 4 relief of increased intraocular tension was obtained by the use of eserine instillation alone.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 120.

THE VALUE OF EYE SYMPTOMS IN THE DIAGNOSIS OF GENERAL DISEASES*

BY

HARALD G. A. GJESSING, M.D.

DRAMMEN, NORWAY

It is often said that the ophthalmologist is merely a specialist. This, however, I hope to be able to contradict. He is and must be—if he really wishes to fill his place—a general physician just as much as the general practitioner. Sir Archibald Garrod impressed this upon us in his speech at Oxford in 1927. His subject was the connexion between internal medicine and ophthalmology.

"What is the difference between a specialist and a quack? Just one little thing. The real specialist thinks always in a general way. He therefore is able to understand the medical process in question. The quack knows merely the symptoms, and is therefore in danger of becoming a symptomatician."

Even if the eye is the most differentiated organ of the body, it is nevertheless merely a single, although a very important, part of the united organs constituting the animal body. In my lecture I hope to prove that a series of symptoms in the eye are due to diseases somewhere else in the body. Thinking of the histology of the eye, it must be evident that the pathology of the central nervous system is rich in eye symptoms. The visual fibre system forms a continuity of axons from the ganglion cells of the retina to its ending in the pole of the occipital lobe. On its way it is in touch with a lot of very important nerve nuclei. Because of this any pathological process here is sure to show itself in the visual organ. In passing, I must call attention to the transient pareses of the eye muscles—especially of the abducens—in tabes, lues cerebri, encephalitis, and disseminated sclerosis. Still more important as a very early symptom in late syphilitic disease is the Argyll Robertson pupil reaction. I think this is the first ocular eye symptom the young medical student is taught when entering a general medical ward. It is superfluous to mention that an exact examination of the pupil reaction may often prevent the overlooking of tabes in recurrent attacks of colic and vomiting.

DISSEMINATED SCLEROSIS

Charcot taught that the cardinal symptoms of disseminated sclerosis were scanning speech, intention tremor, and nystagmus. No greater obstacle to the early diagnosis of this common disease could be met with than a reliance on this statement. This "classical" triad is found complete, according to Marburg, in only about 15 per cent. of all cases. Most of them are immature, "*formes frustes*." In the *Nordisk Medicinsk Tidsskrift* (1929) I published a paper about the eye symptoms of this affection. I emphasized therein that if we still were to accept a diagnostic triad this ought to be: (1) pronounced fatigue following insignificant body exercises and at the same time accentuation of symptoms already present (I hold that the symptom of Uhthoff—passing reduction of vision after a short but quick walk—must come in this class); (2) increase of the tendon reflexes; and (3) passing eye symptoms, frequently with a recurring tendency. W. A. Adie reaches the same conclusion in his excellent work in the *British Medical Journal* (1932). Acute scotomatous retrobulbar neuritis is the most important eye symptom in this disease. Traquair characterizes this neuritis, in his noteworthy Doyne Memorial Lecture in 1923, in the following way. It commences quickly, and is of a changing tendency during its run, ending almost with complete cure of the initial attack. However, it is apt to recur. As a rule it is one-sided, although in my experience I have fre-

quently found it to be bilateral. Not uncommonly this neuritis appears years before the other symptoms of this insidious disease: in the literature there are cases up to eighteen years. The scotoma in this neuritis is always central. In this it differs from the intoxication amblyopias, where the scotomas always commence paracentrally. It may arise not only in an acute but also in a subacute and insidious chronic form. Authors differ widely as regards its percentage of incidence. The lowest figure I have found is 13 per cent., the highest 70 per cent. Personally, I believe 50 per cent. to be the right figure.

Passing palsies of the eye muscles not uncommonly appear, either isolated or together with other symptoms, in multiple sclerosis. They are stated to occur in 25 to 45 per cent. of cases. They may be one-sided or bilateral. Most frequently we find paralysis of the abducens, not uncommonly coupled with paresis of the facial nerve. The nuclei of these nerves are located, as you remember, below the floor of the fourth ventricle. Their root fibres run together with the pyramidal fibres through the pons, which is the common site of selection of the sclerotic plaques. Therefore we frequently notice phenomena from these. Any facial palsy, where all the chief branches are engaged, should always make the physician think of a possible disseminated sclerosis as the underlying cause. Without doubt, a lot of the so-called "rheumatic" facial and abducens palsies are due to this disease in its earliest stages. At least such an origin ought to be kept in mind in all cases of passing eye-muscle paralysees, especially when they are coupled with "rheumatism" somewhere else in the body. Again, we must never forget tabes as a cause. The oculomotor and trochlear nerves are less often attacked by the multiple sclerosis. Their nuclei are situated below the bottom of the aqueductus Sylvii, and thus are above the pons. Recurrent ptosis, however, is often observed together with paresis of the internal rectus muscles. In tabes an isolated paresis of the fourth nerve is not uncommon as a very early symptom.

EYE SIGNS IN SYPHILIS

Argyll Robertson pupils were previously considered as a sure indication of an earlier metaluetic infection. At the present time we know that this phenomenon may arise in the different varieties of encephalitis. This disease is itself characterized by a number of eye symptoms: ptosis, nystagmus, and paralysis of the accommodation are particularly common, and these eye symptoms may make the diagnosis infinitely easier. Time does not allow me to go more fully into details of the pupillary symptoms in general diseases. I merely note that, according to Uhthoff, in more than 80 per cent. of tabetic cases and in general paralysis in about 70 per cent. there is the characteristic reaction of Argyll Robertson. With lues cerebro-spinalis, however, it is comparatively seldom noticed. In this disease an internal opthalmoplegia, combined with palsies of other cerebral nerves, is more often found. Defects of the field of vision—mostly hemianopic—are also commonly seen in cerebral syphilis. A distinct anisocoria is always bound to attract the attention of the physician to a previous infection with the *Spirochaeta pallida*, or—as Sir William Macewen showed so early as 1884—if this is excluded, to an increasing brain pressure, especially a growth in the temporal lobe. On the contrary, an insignificant difference of the pupils with normal reaction is not rare. Probably this is brought about by traumata

* Lecture delivered on January 5th, 1934, in Manchester, at the request of the North of England Ophthalmological Society.

during birth. Irregularities of the pupillary margin—without synechiae—have in earlier days been considered important for the diagnosis of cerebral lues. The importance of this has been overrated, except when it is coupled with disturbances of the pupillary reaction.

Spinal miosis in tabes is frequently noticed owing to affection of the sympathetic in the spinal medulla. It is caused by secondary contraction of the sphincter pupillae, and may be very pronounced. As a rule it is one-sided. In this way it differs from the contraction observed in certain chronic cases of poisoning—especially morphinism. In this latter, however, there is always a normal pupil reaction. In cases of one-sided miosis Horner's syndrome must always be remembered. As you know, this is associated with tumours in the cervical region or even lower—for instance, aneurysm of the aorta—causing paralysis of the sympathetic.

EYE SIGNS IN INFECTIONS

Not only in lues cerebri and metaluetic diseases is the pupillary reaction of great diagnostic importance, but also in a number of other brain diseases. The same is the case with an ophthalmoplegia interna. With a febrile patient a paralysis of the pupil reaction as well as the accommodation may be the single sign of a commencing meningitis. In most of such cases, however, other cerebral nerves will also be affected. These pareses we find most often in luetic and tuberculous inflammation, and more seldom in otogenic meningitis.

I have already mentioned that in certain chronic cases of poisoning—such as morphinism—the size of the pupils may be altered, while their reaction remains normal. In a number of acute toxæmias in febrile diseases there may be paralysis of the pupil. Especially well known is the post-diphtheritic paralysis of accommodation. After an influenza the same occurs, but not so commonly. Both conditions give rise to a bilateral palsy. Cyclitis is not infrequently observed after influenza. Here I may mention that a number of acute infectious diseases, during their febrile stage, are accompanied by a more or less pronounced conjunctivitis. During a measles epidemic, conjunctivitis is a most important diagnostic feature. It may be the first prodromal symptom. Botulism, and meat and fish poisoning, may all be followed by paralysis of the pupil and of other eye muscles. This is also the case with grave gastro-enteritis and paratyphoid fever. The picture is similar to the one seen in acute general atropine poisoning.

METABOLIC DISTURBANCES

It is well known that diabetes mellitus during its progress may be accompanied by passing myopia as well as by transient hypermetropia. Every sixth diabetic has, as a rule, eye complications. Iritis with hypopyon occurs seldom. It is, as regards the general condition, a very severe symptom. All cases of iritis ought, therefore, to be examined for sugar. Sigurd Hagen is probably the first to have emphasized strongly that a transitory hypermetropia never arises in the case of an untreated diabetic. On the other hand, a transitory near-sightedness is not infrequently the very symptom causing the detection of a previously overlooked diabetes. Of special interest is the following case. The myopia reached here the highest figure I have noticed, afterwards completely passing away.

On June 19th, 1920, a gentleman, 67 years of age, called on me to get spectacles. With + 3.5 the vision was 6/4 both eyes. On October 12th, 1921, he returned again, because for the last eight days the vision had faded for distance. With his spectacles for near vision he was just able to read. Used + 6.0. Upon examination normal externa and interna were found. The left eye showed emmetropia, the right - 1.5 myopia. A pronounced positive sugar reaction was found in the urine—also traces of albumin. He was advised to see a diabetes

specialist. During a short space of time a psychosis developed with sensations of inferiority. He died two years afterwards from apoplexy. In the meantime, the myopia had entirely disappeared, and he grew hypermetropic again.

Time does not allow me to enter into the different theories about these passing anomalies. With reference to the myopia I refer to the work of Ask, published in the *Biochemische Zeitschrift* (1913). As to the transitory hypermetropia, I draw attention to Granström's great work in the *Acta Ophthalmologica* (1933). He seeks to prove that a sodium chloride retention is to be found in the lens in diabetics, causing a retention of fluid and alteration of the index. Generally speaking, chemical alterations of the blood—speaking broadly—may be followed by eye symptoms. Of the greatest importance to the general practitioner is, I think, chronic conjunctivitis. Without using tonics we often are not able to cure this type of eye trouble, and there is no doubt that many an eye doctor would have better results in his treatment of conjunctivitis if he were to investigate the colour index of the blood. A remarkable symptom caused by anaemia in chronic conjunctivitis, as well as the fairly common asthenopia, is a slight oedema of the lids. This is mostly pronounced in the morning, disappearing later in the day. This peculiarity is probably caused by the massage effect of repeated blinking.

During the last decade a great many works have been published on the subject of alteration in the blood as an underlying cause of eye diseases. By using the Reid Hunt acetonitril reaction it has been held that certain eye troubles (for example, glaucoma) are due to a hyperiodaemia. This might be of great practical consequence. We should in such cases be most careful in the use of iodides and thyroid extract or other hormone preparations in our treatment of hypertonia and arteriosclerosis. Lagrange is the first to have declared that glaucoma is no local disease, but merely an evidence of a constitutional state. Magitot and Angelucci have formed the opinion that all glaucoma patients are people with diseased vessels. They term such a person "*un vasculaire*," an individual with a disturbed capillary circuit. Others, such as Eppinger, Leube, von Hesse, and Meller, have sought the cause in a disturbance of the equilibrium between the sympathetic and the parasympathetic. They support the opinion by the fact that psychic disturbances aggravate an existing glaucoma, also that glaucoma sometimes, like ophthalmic migraine, improves considerably when the patient is put on a salt-poor diet and gets sufficient exercise to develop free perspiration.

CHANGES IN THE RETINA

Taking the diseases of the retina, we find that in no small percentage they are due to general disease, not uncommonly a disease of the blood. An orbital haemorrhage in infants and with black-red discoloration of conjunctiva and exophthalmos is not infrequently the first sign of a Möller-Barlow's disease, scurvy, or haemophilia. An ophthalmoscopic examination will very often disclose a retinal haemorrhage. All things considered, every haemorrhagic diathesis will tend towards bleeding in the external as well as the internal parts of the eye. Haemorrhages of the retina often appear with purpuric diseases, generally taken. From daily life we know that persons exist who are liable to haemorrhages into the skin after small traumatism. For this reason many a young girl at a dance resents what she considers too brutal a grip from her partner! However, if such a tendency is present in the retinal vessels the results are likely to be much more serious.

Pernicious anaemia is the typical blood disease generally associated with retinal alterations, in contrast to the secondary anaemias. These almost never lead to such. Here

I except the very rare amauroses and amblyopias following in the wake of heavy losses of blood. They are generally seen after abortions and haematemeses—much more infrequently after a normal birth. Their clinical picture is the same as that of embolism of the central artery of the retina. At the peak of pernicious anaemia retinal haemorrhages are very rarely lacking. White degenerative spots are also commonly noted in the oedematous retina. The finding of these alterations is not only of diagnostic but also of prognostic importance. They may disappear without trace when the patient recovers by the use of the liver diet of Minot. In leukaemias—both the myelogenous and the lymphatic—there may be characteristic alterations of the eye. In the lymphatic type as well as in pseudo-leukaemia we may have orbital tumours of lymphatic tissue. For this reason all orbital tumours demand an exact examination of the blood. As you know, the retina often reveals in leukaemia a characteristic light colour, thus contrasting with polycythaemia and congenital heart failure. Any fever of doubtful origin calls for ophthalmoscopy. I just mention the diagnosis of septicaemia, which is so very often difficult. Septic retinitis will, in these cases, make the diagnosis absolutely conclusive. According to the literature it should be observed in about 35 per cent. of all cases. More than one case of malignant endocarditis has been diagnosed by aid of the ophthalmoscope.

DIABETES AND NEPHRITIS

Two very common diseases in which the finding of retinal haemorrhages and exudative spots is of the greatest importance—not only in the diagnosis but also as regards prognosis—are nephritis and diabetes. The double-sidedness of the affection is characteristic of the retinal picture. As a rule it is more developed in one eye than in the other. The papilla shares in the affection to a greater or less extent. In the retina are to be seen oedema, scattered haemorrhages, and spots of white exudates. These last are often arranged like a star in the macular region. The retinitis in nephritis and diabetes is often without any symptom in its earliest stages. In this regard it is different from the usual optic neuritis, where the vision fails very rapidly on account of a central scotoma. Therefore ophthalmoscopy is of such great importance in any case of nephritis, and especially in the chronic cases. In particular, the retinitis in pregnancy may for a long time lack subjective symptoms. Upon examining 8,400 pregnant women Ingolf Schiötz found forty cases of retinitis gravidarum. Of these twenty-seven had chronic nephritis. Several of these had no subjective symptoms. Their vision was 6/6 or about 6/6. The prognosis in retinitis gravidarum, he found, is good, or at least fairly good. The alterations of the retina generally disappear entirely after birth or when an evacuation of the uterus has taken place. On the contrary, a usual retinitis albuminurica is a very bad prognostic sign. Elaborate statistics from large clinics have shown that only 10 per cent. of the affected patients are still alive more than two years after the appearance of the retinitis. And the prognosis is even worse the younger the individual is. According to Ascher the same may be said about the retinitis in diabetics. This, like the iritis, appears only in grave cases.

I must point out that even if the diagnosis of such a neuro-retinitis is easy in some cases, it may in some present very great difficulties. The papillitis may be so developed that the displacement of the papilla may be equal to the choked disk in a cerebral tumour. As these cases not uncommonly may show a star figure at the macula, even the most expert ophthalmologist may go wrong. As in both cases albuminuria may be present, and this periodically even may be absent in granulated kidney, the diagnosis may prove more difficult. Regard-

ing the differential diagnosis, a very exact functional examination is of vital importance. In a real choked disk the vision is, to begin with, less reduced than would be expected in view of the very pronounced ophthalmoscopic picture. With inflammation of the optic nerve the vision is quickly reduced on account of a central scotoma. The pseudo-neuritis of hypermetropia must always be kept in mind. There is no reduction of vision and no central scotoma. Bleedings in the actual pupillary tissue and the surrounding retina speak for choked disk and against pseudo-neuritis.

I cannot here enter further into a description of embolism and thrombosis of the central retinal vessels; I just want to point out that in more than one case the disease apparently starts with these affections. The ophthalmologist often chances on this condition in an elderly patient calling to obtain reading glasses. An exact examination of his urine, heart, and blood pressure is required in such a case. It cannot be emphasized too strongly that an optic neuritis must never be taken for a *morbus sui generis*. This also applies to choked disk, in which latter condition we must remember that more than 80 per cent. are due to an intracranial growth.

HEMIANOPIA

Although hemianopia has been known for a period of about 150 years, its true significance has only been realized since 1855. Barthelmeo Panizza of Padua then proved clinically, pathologically-anatomically, and experimentally that the location of the vision centre is the cortex of the occipital lobe. I cannot here enter into the importance of the interpretation of the different types of hemianopias with reference to a focal diagnosis; I am merely going to mention that the bitemporal hemianopic scotomata are a very early sign of tumours of the hypophysis. I take the occasion to call attention to the excellent work of Traquair, regarding the interpretation of such scotomata. I must, however, be permitted to mention, very shortly, two cases from my own practice, where an exact scotoma investigation decided an otherwise difficult diagnosis.

A very hypochondriacal business-man in his sixties had for a number of years been a worry to his doctor. One day he came to me telling me that he—*mirabile dictu*—was unable to read types of ordinary size, while, on the contrary, he could read the smallest print just as well as before. He dated his troubles from a passing blindness lasting for about one minute three weeks before. Normal external and internal conditions were found. Vision 6/4 O.U. The peripheral field completely normal. Examined with the scotometer of Hiltz a right-sided wedge-shaped hemianopic scotoma was found. It was about 5° degrees in length, and lay with its edge only one degree from the fixation point. It was absolute for colours and relative for white. Upon letting the intelligent man read from right to left, he did so to his own great astonishment.

Here we have a case of the macular hemianopic reading disturbance of Wildbrand. Larger retinal pictures—in this case printed matter—are covered by the scotoma. Small retinal pictures are recognized between the fixation point and the edge of the scotoma facing them. The case shows how careful one must be with the diagnosis of neurasthenia and hypochondria. But for the field examination—with small objects—the fresh complaints of the patient might easily have been indexed among his usual "nervous" ones. In this case, I think, a punctate bleeding was really present in the left cuneus. A few months later he suffered from a new passing amaurosis, showing considerably greater hemianopia.

In the next case I am going to mention mental disease might easily have been diagnosed but for the examination of the ophthalmologist.

A painter, 54 years of age, was sent to me by a county colleague in March, 1920. It was stated that he had had hallucinations for a period of fourteen days after a short

unconsciousness. He imagined he saw the left part of the room filled with a number of people, whom he knew well and could name. He himself had, however, an idea that the whole thing was a "delusion"! He admitted abuse of spirits but denied lies. Upon investigation the eyes were normal, externally and internally. Vision with +1.5, 6/6 O.U. Tension 5/5.5 O.U. By perimetry a typical homonymous hemianopia was found. The entire left half of the fields had disappeared, with only a large rest for the macula left.

The cause of the hemianopia, as well as of his well-developed hallucinations, is one and the same: a focus of some kind in the right temporal lobe. This brain lesion must be subcortically located. It must be so placed that it produces a state of irritation both of his optical centre of memory as well as of his association province. It is further necessary that the cortex cerebri must be undamaged, as it is able to transfer the hallucinations to the consciousness of the patient. Before passing from the subject of the diagnostic value of the hemianopias I must merely mention that quite a few authors (for example, Ingolf Schiötz and Bauer) have demonstrated that passing homonymous hemianopias may arise in a number of auto-intoxications, especially the nephritis in pregnancy.

NYSTAGMUS

In the beginning of my paper I mentioned nystagmus as a link of Charcot's triad in the diagnosis of disseminated sclerosis. Marburg holds that real nystagmus, however, is only seen in at most 12 per cent. of all cases. Nystagmoidal tremblings are, according to Bárány, seen in 60 per cent. of normal people when looking extremely sideways. But even if this symptom is of no especial importance in the diagnosis of the above-mentioned disease, it is, however, as expressed by the Belgian Coppex, "*Une importance considérable en otologie, en neurologie et en hygiène générale.*" When he does not add "*en ophthalmologie*," although it is an eye symptom, it is in my opinion to emphasize that the specialist must never be one-sided! He must never lose sight of the organism in favour of the organ. The otologist Adrian de Kleijn of Utrecht is probably the man who has done the most valuable work on nystagmus next to Robert Bárány and Mario Camis. He meant to have a good reason for sacrificing two years in the study of ophthalmology before becoming purely an otologist.

This is not the place to enter upon the large subject of general medicine. I merely mention that in this domain the British surgeons have produced works of the highest lasting value. Thus the English doctor Gillot, in Sheffield in the year 1858, described "miner's nystagmus"—that is, three years ahead of the Belgian ophthalmologist Deconde. As we in Norway have no coal mines I have not personally seen this disease. Later on, very important studies on this subject were published in different countries. From the German side I only mention Johannes Ohm; from the British, Maitland Ramsay, Priestley Smith, sen., Elsworth, Stanley Percival, and Maurice Bartholomew. Every one of them has held that it is seen particularly with bad mine hygiene. In this connexion Percival's statement regarding blue-blindness preceding the nystagmus is of the utmost hygienic importance. That shock releases a latent nystagmus was demonstrated during the world war by Elliot and Stirling. Priestley Smith has shown that certain poisons (for example, iodoform and morphine) may play a part. This also indicated that the cerebrum must have some nystagmogenous influence. The fact that it is also seen in febrile diseases points in the same direction. Before leaving nystagmus I cannot but mention the great credit due to Bárány by the finding of caloric nystagmus in the diagnosis of a number of brain diseases, especially acoustic tumours. I also call your attention to the fact that Igersheimer and Heine have found that in not a few cases of congenital nystagmus the Wassermann reaction is positive. They

hold that vigorous antisyphilitic treatment has influenced this nystagmus in a favourable direction.

EYE SYMPTOMS IN POISONING

Time prevents me from entering into the eye symptoms which follow a number of poisonings. I merely mention a few points about santonin poisoning. Here the ophthalmologist may happen to fill the important role as legal-physician. In the case of such poisoning—as also with misuse of digitalis—xanthopsia not infrequently appears. Less well known to most of you may possibly be that Bruneche has described hallucinations of red vision, rhodopsia, with this poisoning: "Everything is floating in blood"! At the same time the poisoned person describes terrible murder scenes!

Acute poisoning from methyl alcohol is well known in the so-called "dry" countries. Acute gastro-enteritis supervenes—often some little time after the drinking. In addition to this a rapidly developing amaurosis, resulting from an acute degeneration of the ganglion cells of the retina, and a secondary atrophy of the optic nerve, is often observed. In the most pronounced cases an amaurotic loss of the pupil reaction is seen. The extrinsic eye muscles are always intact. In this respect this poisoning differs from the similar picture in meat poisoning. Less well known is perhaps that clinical picture described by Louis Ziegler in 1920. In Philadelphia society a number of young society women were attacked by an insidious atrophy of the optic nerve. Over a long period they had taken eau-de-Cologne poured on pieces of sugar. The American scents at that time contained 25 per cent. of methylated alcohol. These infinitesimal doses were not sufficient to produce the common poisoning picture. Where the Wassermann reaction is negative and tumour may be excluded in a chronic optic atrophy, it may therefore be of interest to examine for formic acid in the blood and urine. It is also necessary in cases of chronic retrobulbar neuritis to think of poisoning with lead or carbon disulphide, especially in cases of concentric shrinkage of the field. I pass over the acute quinine amaurosis in women endeavouring to cause abortion.

DEFICIENCY DISEASES

Hemeralopia must of necessity be connected with a retinal nutritive disturbance—not yet quite detected. Here I exclude anatomical retinal diseases such as retinitis pigmentosa or siderosis. Only during the last few years has the cause of this rather obscure condition been found. It is due to a lack of vitamin A. This circumstance explains why cod-liver oil has such a good effect, and why the spring fast-time predisposes to the outbreak of the sickness. Such night-blindness is followed, more or less, by xerosis conjunctivae. Suitable diet cures the trouble.

Much more dangerous is keratomalacia in infants. It was the great paediatric star of Breslau, Czerny, together with Keller, who introduced the term "*Milchmährschaden*." By this is meant that the infant is supernourished on carbohydrates. It is all right for three to six months, or even longer. Then a conjunctivitis suddenly appears. To begin with it does not look dangerous. But an observant surgeon will even then notice the white spots near the limbus, described by Bitôt. This xerosis rapidly spreads, and if the case is not properly treated necrosis of one or both corneae may occur. In Norway this disease is seldom observed. In Denmark it was relatively frequent during the war. Here it was described by Professor Block and Edmund Jensen. But its real cause was first found by Sjunte, and later studied by Rønne and Blegvad. Supported by the findings of Monrad they have demonstrated the almost magic effect of sweet milk together with carrots and a little cod-liver oil. It may, though seldom, attack adults living on a diet poor in vitamin A. The aetiology of the phlyctenule is greatly disputed.

Some, such as Maitland Ramsay, hold entirely too bigoted a view that it is caused by a chronic digestive disturbance. Others hold, quite as certainly, that the singular cause is scrophulo-tuberculosis. One thing is sure. Bad hygiene plays a great part in its pathogenesis by preparing the soil. Wessely has emphasized that patients suffering from phlyctenular kerato-conjunctivitis are liable to catch catarrhs because of being supersensitive. However, the diagnosis of phlyctenular conjunctivitis must always remind the doctor that the child does not belong to a robust type.

OCULAR TUBERCULOSIS

A uveitis must always be regarded as a sign of a general disease when no external infection can be found. Because of that a uveitis—and also the much more infrequent scleritis—is always reason enough for a close internal examination. There is hardly any general disease which may not be the cause of it. But tuberculosis and syphilis are the predominant causes. The investigations of the last few years by Schieck and Werdenberg seem to have proved that ocular tuberculosis must not be regarded as a disease *sui generis*. It is to be considered as a metastasis in the eye. As a rule the glands at the hilus are the starting-point. As we do not know for certain what "rheumatism" really is, it is very probable that a number of cases of so-called "rheumatic" uveitis are of a tuberculous origin. The entire chapter of "rheumatism" has now to be recast. I may recall that a disease such as erythema nodosum was regarded as "rheumatismus acutus mitis cutis." Probably the general opinion is that it is a toxic skin affection in a tuberculous patient, of the same kind as von Pirquet's skin reaction. It is held that it appears simultaneously with the manifestation of a previously latent tuberculosis of the bronchial glands. But, on the other hand, we must remember that in a certain percentage the reaction of von Pirquet is negative. It is advisable to maintain the old cause in those cases. In the same manner we must still believe in "rheumatic" uveitis in a not insignificant percentage. In this group we also include the gonorrhoeal cases, and these must be considered as due to metastatic inflammation. Thus any violent iritis in an adult—especially combined with pain in the joints—ought always to direct the physician's attention towards a Neisser infection as the cause.

This is not the place to go into the differential diagnosis between tuberculous and syphilitic iritis. The Wassermann reaction has greatly facilitated the diagnosis as regards syphilis when the clinical picture is typical. On the other hand, it may be more difficult in all cases to be quite sure about the origin of a tuberculous iritis. Axenfeld and Stock particularly deserve the greatest praise for their minute experimental investigations of uveal tuberculosis. By injecting attenuated tubercle bacilli into the ear veins of rabbits tuberculous nodules were developed. The retina remained histologically free, just as in military tuberculosis. They showed also how the not uncommonly recurring haemorrhages in the corpus vitreum in young—especially male—persons were caused by a periphlebitis. Often they succeeded in thus demonstrating directly a tuberculous process. In others they had to suppose as cause a toxic effect. The most recent explanation by Meller, in regard to sympathetic ophthalmia, is that it is due to attenuated tubercle bacilli. He has supported this clinically as well as experimentally.

MISCELLANEOUS CONDITIONS

During later times the importance of the internal secretory disturbances in aetiology and pathogenesis have been minutely studied. The description of these examinations would call for an entire evening. I must restrict myself to mention of the vast importance of eye symptoms in the diagnosis of tumours in the region of the hypophysis. In diseases here the ophthalmologist will be the

best helper, not only to the physician, but also to the surgeon. An examination of the field of vision is always strongly called for where amenorrhoea exists without any "physiological" reason, or in impotence of a too early appearance. It is hardly too much to say that but for his ophthalmological helper Harvey Cushing would not have been able to build up his splendid technique as a brain operator.

It is still disputed whether the syndrome osteopospathyrosis idiopathica—fragilitas ossium—is due to an inherited endocrine disturbance. This ailment is characterized by the triad: persistent blue sclera, fragility of the bones, and early labyrinth deafness. In any case the school physician finding a pupil with blue sclerae must later on have his attention directed towards the ears and bones.

The importance of trauma as a releasing factor with luetic parenchymatous keratitis is still *sub judice*. At least so much is certain, that it is not merely the vagrant spirochaetes in the lymph streams in the corneal tissue which are the cause. If so, it would be supposed that an energetic antisyphilitic treatment would prevent an attack of the keratitis in the second eye. On the contrary, this is rather the exception than the rule. There must therefore be an unknown *x*. Supported by a very minute investigation, clinically as well as serologically—after the method of Abderhalden—Zederkreutz, Johanson, and Enroth have attempted to prove that an endocrine disturbance may be found in more than 60 per cent. of all cases of luetic parenchymatous keratitis. Investigations—particularly German ones—have demonstrated that about 90 per cent. of all cases of deep keratitis are due to lues, especially congenital. According to von Michel tuberculosis is the cause of the remaining 10 per cent. In our time of accident insurance it is certainly correct to accept Schieck's and von Szilly's opinion as to questions about the importance of trauma in keratitis parenchymatosa. Parenchymatous keratitis is due to two factors which act together—infection + disturbed metabolism. An incidental cause—such as a trauma—releases the disease. Before finishing my remarks on the disturbances of metabolism and consequent eye symptoms, I merely mention the great diagnostic value they have in Graves's disease.

M. Piani (*Thèse de Paris*, 1934, No. 29) states that in spite of the excellent climate, temperate winters, and mild autumns Corsica suffers considerably from three serious epidemic diseases—namely, malaria, undulant fever, and tuberculosis. The almost complete absence of hygiene, due to the poverty and lack of education of the native population, is to a large extent responsible for their spread. Malaria has always been prevalent in Corsica, especially on the east coast, where it has assumed alarming proportions. The average parasitic index for the whole of Corsica is 18.56, and the splenic index 38.64. These figures, however, do not represent the true state of affairs, as they are merely the result of investigations carried out in certain parts of the island. Undulant fever is also remarkably prevalent. In 1929 the annual average number of cases was estimated at 200, while in 1932 600 cases were notified. Corsica is one of the French departments which pay the heaviest tribute to tuberculosis. During the period 1925 to 1930 the deaths from the disease have more than doubled (140 deaths in 1925 and 291 deaths in 1930). The principal causes of the spread of tuberculosis are the almost complete absence of anti-tuberculosis services, the yearly return of a large number of Corsicans who have contracted tuberculosis in France, the ignorance of the most elementary rules of hygiene, and the failure to diagnose numerous cases which are mistaken for undulant fever or malaria. Seasonal diseases such as pneumonia and pleurisy are not uncommon, owing to lack of precautions against changes in the winter. As regards mental diseases, constitutional states such as idiocy, imbecility, and cretinism are the only conditions which are at all frequent.

THE AUTONOMIC NERVE SUPPLY OF THE DISTAL COLON

AN ANATOMICAL AND CLINICAL STUDY

BY

E. D. TELFORD, B.Ch., F.R.C.S.

PROFESSOR OF SYSTEMATIC SURGERY, UNIVERSITY OF MANCHESTER

AND

JOHN S. B. STOPFORD, M.D., F.R.S.

PROFESSOR OF ANATOMY, UNIVERSITY OF MANCHESTER

It appears certain that the effective treatment of some diseases of the distal colon, such as Hirschsprung's disease and some forms of constipation, lies in the performance of a sympathectomy. This noteworthy advance in surgery, based as it is on the foundation laid by Gaskell, Langley, and Anderson, is due to the work of many surgeons within recent years. Important contributions have been made by Wade, Trumble, Learmonth, Royle, Rankin, Adson, and others.

While there is general agreement that the treatment of such diseases of the colon as we believe to depend on autonomic imbalance must be by sympathectomy, there exists a great diversity in the methods and technique of the operation. There are wide differences in the views of surgeons as to the mode of attack, and these differences are reflected in the variety of operations which have been employed. Excision of the lumbar sympathetic cord, ramisection of the medially directed rami of the cord (lumbar splanchnic nerves), resection of the presacral nerve, and perivascular sympathectomy of the "aortic" plexus and of that around the inferior mesenteric artery have all been employed either singly or in various combinations. Moreover, some surgeons have reported cases in which their operation has been restricted to the left side, a method which, although success has been reported, is obviously incomplete. The distal colon must on embryological and anatomical grounds derive a symmetrical supply from the autonomic system.

Although good results have been claimed for all these operations it is much to be desired that a standard method be found; such method should be, as far as is possible, physiologically sound, easy, and safe of execution. It is unlikely that all of the above methods fulfil these postulates, and indeed some of the routes are open to the criticism that they may involve destruction of sympathetic and parasympathetic fibres alike; a result which, if our present view of autonomic function be correct, is plainly undesirable.

It is evident, therefore, that any inquiry into the best route must begin with a consideration of the course by which the sympathetic and parasympathetic fibres reach the distal colon. The ultimate distribution of each is mainly, probably entirely, by a perivascular course along the inferior mesenteric artery and its branches, but the route by which each approaches the artery is not the same. There is general agreement as to the sympathetic supply.

ANATOMICAL SECTION

It is convenient first to review the arrangement of the sympathetic fibres in the lower part of the abdomen and pelvis, since this investigation has confirmed a number of points.

Sympathetic Supply

Extending downwards from the coeliac plexus and its extensions on the antero-lateral aspects of the aorta, on each side, are usually one, two, or three fine bundles of nerve fibres, to which the name intermesenteric nerves

has been applied. These nerves are joined laterally by rami from the upper lumbar ganglia, or adjoining parts of the lumbar sympathetic cord, of their own side. Trumble¹ figures two rami on each side, but although this seems to be the commonest arrangement, the number was found to be variable, like the number of lumbar ganglia. Sometimes as many as four rami are to be observed on one side, and they do not as a rule in man converge upon the inferior mesenteric artery as shown in Trumble's figures, but join primarily the intermesenteric nerves in front of the aorta. These rami are not infrequently referred to as the lumbar splanchnic nerves, and it is evident from both dissections and surgical experience that, when three or four are present, it is the upper two on each side which are principally concerned with the innervation of the distal colon. On the right side the lumbar splanchnic nerves approach the intermesenteric nerves from behind the inferior vena cava. There are usually two or three slender strands of nerve fibres passing across the aorta to connect the intermesenteric nerves of the two sides; these strands are often to be seen both above and below the point of origin of the inferior mesenteric artery. The fibres which connect the intermesenteric nerves of the two sides do not form a plexus, and our observations support the view recently emphasized by Davis² that a true aortic plexus does not exist.

The inferior mesenteric plexus is formed by a number of sets of fibres arising from the medial sides of the right and left intermesenteric nerves, and these fibres form a dense network around the inferior mesenteric artery about half to three-quarters of an inch beyond its origin. It is clear from the dissections that the inferior mesenteric plexus receives sympathetic fibres from both sides, as is to be expected on developmental and other grounds. It is also evident that the source of these fibres is the upper lumbar ganglia, and not to any important extent from the intermesenteric nerves descending from the coeliac plexus. From the dense plexus around the stem of the inferior mesenteric artery perivascular fibres can be traced along all the branches of this vessel.

Below the origin of the inferior mesenteric plexus three descending bundles are usually to be found, which converge to form the hypogastric plexus. The two lateral trunks are direct continuations of the intermesenteric nerves after they have contributed fibres to the intermesenteric plexus. The left lateral trunk passes down behind the inferior mesenteric artery or its branches. The intermediate or middle trunk has more complicated connexions. It is commonly connected with the intermesenteric nerves of the two sides, and, in addition, communicates directly with the inferior mesenteric plexus. Careful dissection shows that some of these fibres are definitely descending through the inferior mesenteric plexus, but the arrangement of others suggests that they are ascending to the plexus. Dissection cannot definitely decide the origin of these fibres, and several possibilities must be considered.

1. They might be sympathetic fibres from the sacral or lowest lumbar ganglion ascending to the plexus.
2. It is possible for them to be parasympathetic fibres, from the sacral splanchnic nerves (nervi erigentes), which pass up to the colon through the hypogastric plexus.
3. Fibres from both the above sources may be represented.
4. It seems more probable that they are really descending fibres arising from the ganglion cells in the inferior mesenteric plexus, and that the arrangement suggesting that they are passing up to the plexus is misleading.

The most important question from a clinical aspect is whether these fibres are parasympathetic or not. At the outset of this investigation we thought it probable that the parasympathetic supply to the distal colon reached the

inferior mesenteric artery through the hypogastric plexus, but the fibres under discussion appeared to be insufficient for such an extensive distribution, and, furthermore, it was impossible to trace any connexion between them and the sacral splanchnic nerves. While it is impossible to exclude the hypogastric plexus as a path for a few parasympathetic fibres to the colon, it is clear from subsequent investigations that this is not the main source, and it can only supplement to some extent the chief path which is to be described. If the middle trunk of the hypogastric plexus conveys sympathetic fibres to the inferior mesenteric plexus it is also certain that this source is quite unimportant compared with the much larger supply from above through the upper lumbar splanchnic nerves of the two sides.

It is unnecessary to refer further to the hypogastric plexus, as our findings agree so closely with those recently

To show the sympathetic and parasympathetic supply to the distal colon: I.N., intermesenteric nerves; L.S.N., lumbar splanchnic nerves; I.M.P., inferior mesenteric plexus; P., parasympathetic fibres for distal colon; H.P., hypogastric plexus.

published by Elant¹ and Davis.² Inferiorly the hypogastric plexus divides, and each division becomes continuous with the pelvic plexus which is joined by the pelvic splanchnic nerves (parasympathetic). We have not attempted to define the sacral roots from which the parasympathetic fibres arose in each of our dissections.

The Parasympathetic Supply

It is when we come to consider the parasympathetic innervation that we find our knowledge to be much more vague. Only by more exact information of the course of the parasympathetic fibres can we ensure their safety at operation, and it was with this object that the present inquiry was undertaken.

Many anatomical textbooks merely mention that the distal colon receives parasympathetic fibres, and none appears to give any accurate information on this subject. Quite recently Maclaren Thompson³ has stated with reference to the superior and inferior mesenteric plexuses: "It is not yet established whether these sympathetic plexuses in man are joined by parasympathetic fibres

from the vagi (cranial outflow), from the pelvic splanchnics (sacral outflow), from both, or from neither." In adjoining paragraphs he wisely indicates that the arrangement in different animals has been found to be "far too variable to be applied indiscriminately to man."

As just stated it has not yet been proved in man whether the parasympathetic supply for the distal colon comes from the vagi (cranial outflow) or from the pelvic splanchnic nerves (sacral outflow). Nevertheless it seems highly improbable, from our knowledge of the distribution of the vagi within the abdomen, and our own dissections, that the cranial outflow provides the parasympathetic supply to the distal colon. In the first place, the number of vagal fibres which pass from the stomach to the coeliac plexus is quite inadequate for such a possibility; and secondly, the only path by which such fibres could travel to the distal colon seems to be the intermesenteric nerves, which contribute few, if any, fibres to the inferior mesenteric plexus. A third point is the evidence submitted below, in which it is shown that a definite contribution to the distal colon comes from the pelvic splanchnic nerves. Although absolute proof of a sole supply of parasympathetic fibres from the sacral outflow is lacking, there seems to be no doubt that the main supply is from this source.

It has been noted previously that at first sight it would appear likely that the parasympathetic fibres from the sacral outflow would extend upwards through the hypogastric plexus to the inferior mesenteric plexus. The possibility of this course for a few parasympathetic fibres has been discussed, and it cannot be eliminated, but the number of fibres which could take this route seems inadequate for such an extensive distribution, and another path must be sought.

In the first case this obviously more important path was discovered accidentally, but its constant occurrence and arrangement has been verified by a number of subsequent dissections. On examining closely the lower part of the hypogastric and pelvic plexuses a small bundle of fibres can be seen on their ventral aspect on each side. The two bundles are easily separated from the main plexuses and can be traced upwards; where they converge to meet and fuse to the left side of the hypogastric plexus. The small trunk, formed by the fusion of the two bundles, can be followed upwards and to the left over the left common iliac artery to the inferior mesenteric plexus, which it joins about one to one and a half inches distal to the origin of the artery from the aorta. On joining the inferior mesenteric plexus the fibres mix with the sympathetic fibres, but with care it can be seen that these parasympathetic fibres extend as a perivascular plexus mainly on to the left colic artery and its ascending and descending divisions. Near the point where the main parasympathetic trunk crosses the left common iliac artery a leash of fibres arises from its left side, and can be traced to the sigmoid and superior haemorrhoidal branches of the inferior mesenteric artery. These fibres are evidently for the supply of the pelvic colon and rectum, and can be followed to these parts of the alimentary canal. In the case of the rectum it appears probable that these fibres provide only a supplementary parasympathetic supply, since the main source is more direct, and comes from the pelvic plexuses as described in anatomical textbooks.

The fibres travelling upwards in this way to accompany various branches of the inferior mesenteric artery to the distal colon have been described as parasympathetic, and this statement can be confidently made, since it is possible, by means of a careful dissection, to follow the fibres centrally through the pelvic plexuses and to demonstrate continuity with the pelvic splanchnic nerves. In the course of the dissections it was found best to isolate the

parasympathetic fibres at first below as they lie upon the pelvic plexuses, and from this point to trace them upwards. If the dissection is made in the reverse direction it is easy to damage the fibres or to fail to find them. Thus it seems quite clear that the main path for the parasympathetic fibres to the distal colon is independent of the presacral nerve, and consists of a small but definite trunk, which comes from the pelvic splanchnic nerves of the two sides and, after piercing the pelvic plexuses, ascends on the left side of the hypogastric plexus.

CLINICAL APPLICATION OF THESE FINDINGS

Several surgeons have attempted sympathetic denervation of the distal colon by operation on the presacral nerve, and/or a perivascular stripping of the origin of the inferior mesenteric artery carried for a distance along this vessel, which ranges, in different descriptions, from a half to one inch.

Apart from the very important fact that presacral neurectomy should not be done for this purpose in males, it is further evident that the operation might involve section of the parasympathetic supply of the distal colon. This undesirable sequel might happen if the surgeon were to carry out the excision too generously in a lateral direction or, conversely, if by any chance the parasympathetic fibres were running more medially than normal. Further, if a perivascular stripping of the inferior mesenteric artery be pushed too far along the vessel the parasympathetic supply will be destroyed.

A second method, which has been followed by other workers, is the excision of the lumbar sympathetic cords. This gives excellent results in cases of Hirschsprung's disease, and in this respect our experience has been in entire accord with the results of other and older workers. But it is at least open to question whether the beneficial results are not due entirely to the section of the lumbar splanchnic nerves, which must be divided if the excision of the sympathetic cord is carried to a proper height. It is, we think, sufficient to divide only the lumbar splanchnics; a method first suggested by Wade, who, however, at least in his earlier cases, attacked only the left side, and laid stress on the division of the white (preganglionic) ramus from the first lumbar nerve.

It is often urged, and with some justice, that sympathectomy, as at present performed is unnecessarily destructive. That this is so is due to the want of more exact anatomical knowledge. The surgeon is driven to do more than is requisite and necessary in order to ensure that enough is done. With increasing knowledge and experience deliberate ramisection should tend to replace the cruder methods of cord ganglionectomy.

It may be possible to denervate the arm of its sympathetic supply without presenting the patient with an unwanted and disfiguring Horner's syndrome. Similarly, a simple deliberate section of the lumbar splanchnic rami will, we believe, prove sufficient to cure cases of Hirschsprung's disease without involving the unwanted by-product of a permanent vaso-dilatation of the lower extremities.

This anatomical inquiry is, we think, a definite contribution to our knowledge of the innervation of the distal colon, since it has not only displayed for the first time some exact information about the parasympathetic supply, but has thrown further light on the safest and surest route by which the sympathetic supply may be cut without endangering any fibres of the parasympathetic.

A STUDY OF HYSTERECTOMY BASED ON THE AFTER-HISTORIES OF 112 CASES*

BY

PETER McEWAN, M.A., M.B., F.R.C.S.Ed.

HONORARY SURGEON, BRADFORD ROYAL INFIRMARY, AND HARTLEY HOSPITAL, COINE

This investigation was undertaken with a view to finding out how far these patients were satisfied with the result of their operation; how severe their menopausal symptoms were; whether the removal of the ovaries along with the uterus was justifiable; how far sex relationship and sexual feelings were altered; and whether obesity frequently followed. Some other findings of interest are recorded. One hundred and ninety-five consecutive cases of hysterectomy operated on in hospital by the writer during eight years received a single invitation to attend in the spring of 1933; of these 112 attended—a fairly representative number, considering change of address, weather, sickness, etc.—and were submitted to a questionnaire with their old notes in front. The analysis of the tabulated facts is as follows.

Indications for Operation

Carcinoma of cervix uteri...	1
Malignant disease of corpus uteri	2
Fibroids	37
Post-menopausal haemorrhage	2
Placental mole	1
Double pyosalpinx	1
Double retroperitoneal cysts	1
Endometritis, salpingo-oophoritis, and endometriosis	67

Nature of Operation

Vaginal hysterectomy	4
Subtotal hysterectomy	98
Panhysterectomy	10
Both appendages removed	91
Neither appendages removed	12
Appendages of one side removed	9
Appendix removed	65
Appendix not removed	12
Appendix removed previously	15

Age Incidence

20-25	2	40-45	31
25-30	5	45-50	14
30-35	19	50-55	11
35-40	28	55-65	2

Successful and restored to work	109
In indifferent health	3

Menopausal Phenomena

Negligible or non-existent	29
Slight	17
Moderate or mild	27
Severe	35
Post-menopausal cases	4

Nature of Menopausal Symptoms

Flushings and sweatings	83
Headache	30
Dizziness	10
Irritability	7
Nervousness	11
Mental upset	1
Miscellaneous	7

In 11 cases only one of the above symptoms was present; in 42, two only; in 20, three only; in 6, more than three; in 29 the symptoms were negligible; and 4 were beyond the menopause.

Effect on Weight

Stationary	25
Slight increase	50
Considerable increase	29
Loss of weight	8

INDICATIONS FOR OPERATION

The precise indications for hysterectomy vary according to the point of view of the surgeon. In this series, for example, there is only one case of cancer of the cervix uteri; nearly all cases during those eight years were treated with radium. Some uncomplicated cases of severe menopausal haemorrhage were also treated with radium. Certain cases of fibroids were treated by myomectomy instead of hysterectomy. On the other hand, the group of cases classed as endometritis, salpingo-oophoritis, and endometriosis is perhaps relatively large, and calls for explanation. It is drawn from women who present themselves in fair numbers at the out-patient department. Their health is being steadily undermined by pelvic pain, dysmenorrhoea, and menorrhagia; backache, leucorrhoea, frequency of micturition, and dyspareunia (if inquired about) being often added to the picture. The menstrual period has become a burden; each period is a blow to their physical and nervous energy, and they recover incompletely before the next blow arrives. They drift steadily towards ill-health, and become debilitated, unhappy, and neurotic. To these women, in selected cases, hysterectomy is a tremendous boon, and restores them to comfort and fairly sound health.

Care must be taken to exclude the neurotic woman who has centred her neurosis upon her pelvic organs, and to exclude cases in which less drastic treatment may be effective. Hysterectomy must not be resorted to without the intelligent consent of the patient, and, if married, of her husband, and the co-operation of her doctor. The fact that these cases are far commoner in hospital than in private work shows how greatly the conditions of life react upon pelvic symptoms; no doubt a sea voyage and an easy healthy life would relieve many. Hysterectomy is regrettable, but the verdict of almost every woman in this group of sixty-seven cases was unhesitatingly, often enthusiastically, in praise of the operation. Many of them have had one or more children, and date their troubles from infection at childbirth. Not a few have had one or more operations, and are in danger of "post-operative neurasthenia."

The pathology of the condition is complicated. Most of the specimens were microscopically examined, and hyperplasia of the uterine mucosa, small-cell infiltration of the uterine wall, and endometrioma of the ovaries were among the conditions most frequently reported. It may

be argued that where the uterus is not greatly enlarged an artificial menopause induced by x rays or radium would suffice, but, as Green-Armytage¹ points out, the difficulty of exact diagnosis between endometrioma, malignant disease, inflammatory conditions, and fibroids, is an argument of weight in favour of operative treatment. When the uterus has fulfilled its essential function of child-bearing or ceased to be capable of producing children, and the pelvic organs have become a tax on a woman's physical and mental well-being, hysterectomy is an invaluable method of restoring health, and should not be delayed until prolonged pelvic trouble has inflicted serious permanent damage on the nervous system.

TYPE OF OPERATION

Much discussion has recently centred on this subject. Vaginal hysterectomy, though largely in disuse, gave in the four cases a speedy convalescence; it is apt to throw more strain on the surgeon than on the patient. Subtotal hysterectomies numbered ninety-eight: panhysterectomies ten; where the cervix was badly torn panhysterectomy was preferred. It may be noted that leucorrhoea was cured in forty-five out of the fifty cases where it was complained of, and its cure did not seem to depend on whether the cervix was removed or not. The appendix was always removed if still present, unless there was reason for haste; to leave it as a routine procedure seems to me a serious and, I might almost say, a culpable omission.

The question of whether ovarian tissue should be left or not when hysterectomy is performed may be regarded as still *sub judice*, although the trend of recent opinion is distinctly in favour of conserving ovarian tissue. In this series the menopause was severe in seven cases out of seventeen (41 per cent.) in which ovarian tissue was left, and in twenty-eight cases out of ninety-one (32 per cent.) in which both ovaries were removed. Obesity occurred in eight cases (48 per cent.) in which ovarian tissue was left, and in twenty-one (23 per cent.) in which both ovaries were removed. So far as this series of cases is concerned, the conservation of ovarian tissue did not appear to influence for good the severity of the menopause, the occurrence of obesity, or the loss of sexual feeling. In many cases of hysterectomy where the ovaries are not removed, it appears that the latter, their main objective the uterus being gone, atrophy sometimes at once, often within a year or two, sometimes later. I have seen a woman of 50, who had undergone hysterectomy twelve years before, have a secondary menopause begin as late as at 48, and continue still very troublesome two years later. This small series of cases does not support the view that ovarian tissue should be conserved at the operation of hysterectomy.

MENOPAUSAL SYMPTOMS

It would be unfair to expect in a series such as this, where the condition of the patients was such as to lead to the performance of hysterectomy, that the artificial menopause would be nearly as uneventful as in an equal number of average healthy women. I believe that the woman who has lived a healthy life, physical and mental, passes through the menopause with comparatively little discomfort.

In this series the menopause was found to be negligible in 27 per cent., slight in 16 per cent., moderate in 25 per cent., severe in 32 per cent. There was one very constant feature in the cases where the menopause was severe; these patients had suffered repeated trauma to the nervous system, often for years, either from severe dysmenorrhoea, or a hard and overwrought life, or other cause (sometimes

marital) of chronic nervous exhaustion. Anaemia, even a high degree of anaemia, did not *per se* favour a stormy menopause. No other common factor was found to exist in these cases, and there seems good ground for concluding that the essential cause of a severe menopause is an exhausted nervous system.

OBSIDITY AFTER HYSTERECTOMY

The figures show that obesity is by no means a necessary sequel of this operation, a considerable increase in weight occurring only in twenty-nine cases (25 per cent.). A further analysis showed that obesity had no relation to the severity of the menopause, the persistence of sex feeling, or the conservation of ovarian tissue. The menopause was severe in ten cases (34 per cent.), moderate in six (22 per cent.), slight in five (17 per cent.), negligible in eight (27 per cent.). Sexual feelings were normal in seven out of seventeen (41 per cent.), lessened in six out of seventeen (35 per cent.), and disappeared in four out of seventeen (24 per cent.). Obesity occurred in eight of the twenty-one cases in which ovarian tissue was left (38 per cent.), and in twenty-one out of the ninety-one "clean sweep" operations (23 per cent.). But it occurred in twenty out of the fifty-four cases under 40 years (37 per cent.), and in nine out of the fifty-eight cases over 40 (15 per cent.). So that patients under 40 were more than twice as liable to obesity as those over that age. In certain cases the cessation of the debilitating menstrual period, apart from any specific action of the reproductive hormones, may tend to an increase in weight. Dr. Margaret Sharp informs me that at the Eldwick Sanatorium patients almost always lose weight during menstruation, even as much as 2 lb. during a menstrual period of a week's duration. I believe that if one of the well-known "slimming" diets were put in the hands of those patients, many of them could thereby compensate for the change in metabolism, and would willingly take the trouble to do so.

HYSTERECTOMY AND SEX INSTINCT

My interest in this aspect of the subject was aroused ten years ago, when, after I had recommended hysterectomy for a fibroid, a friend of the patient said: "I am sorry you have suggested this operation, because ever since you did it for me I have lost my sex feelings." I then became interested to know in what proportion of cases these were lost. It was not, of course, possible to ask all the patients, the unmarried ones, widows, etc. In the sixty-four cases in which an answer was possible, these feelings remained unchanged or normal in thirty-four (53 per cent.), increased in three (5 per cent.), diminished in eleven (17 per cent.), and disappeared in sixteen (25 per cent.). I am not acquainted with any figures relating to the effects of the normal menopause, but I doubt if they would be better than these. Simply from the point of view of sex, the disadvantage of an early menopause may be thus stated: that in those women who are destined to lose their sex feelings at the change of life it is a matter for regret to antedate this loss by five, ten, or twenty years, but it is certain that no such loss need necessarily occur.

Is a woman unsexed by hysterectomy? In order to reply we must ask what constitutes a woman? If it be the capacity to bear children, seeing that in the great majority of these cases this capacity is lost before operation, it cannot be said that hysterectomy unsexes them. If the power to consummate marriage be the test, they are not unsexed, since many women after the "clean sweep" operation retain their sex feelings and marital relationships as before. I had occasion to perform a

hysterectomy for fibroids with removal of both appendages in a woman of 53. Her husband came specially to ask me if the operation would rid her of her amorous tendencies, which greatly embarrassed him. She was the mother of six children. Two years later he informed me that she was unchanged in this respect.

It is natural to think that a complete set of ovaries and the associated endocrine glands is necessary for the building up of the complex emotional nature of woman, although in the hermaphrodite this view is difficult to maintain. A male pseudo-hermaphrodite came to consult me because she wanted to get married, and was aware (never having told anyone) that she was part man and part woman. I removed a rudimentary penis and a gland from the right "labium," shown by the microscope to be a testis, and so made her a fairly presentable female. Pelvic examination showed that she possessed neither uterus nor ovaries; but she had the emotions and sex attractions of a woman, and soon after she married. It is hard to explain this case, or the fact that removal of uterus and ovaries abolishes the sex instinct in some women and not in others. That femininity can develop without uterus and ovaries, and can remain after their removal, appears certain, and it must therefore be concluded that hysterectomy does not unsex a woman.

NEUROSIS AFTER HYSTERECTOMY

Hysterectomy is peculiarly exposed to the charge of setting up a post-operative neurosis. It is performed often at the time of the menopause, the unstable period of a woman's life, and in any case brings about an artificial menopause. The subjects are unhealthy, sometimes physical wrecks, and the conditions of life to which they return, as regards work, poverty, family cares, etc., are often unfavourable to a proper convalescence.

Certain types of neurosis may be referred to. Morbidity owing to loss of the reproduction organs should be prevented by careful explanation before operation. Hysterectomy is the most important operation that can be performed upon a woman, and calls for the full and informed consent of the patient, and her husband (if any), and the co-operation of her doctor. To the patient it means the cessation of the menstrual flow, a definite landmark often regarded as separating youth from age, and one of which she is reminded month after month. It means the loss of the capacity to conceive. The maternal instinct (represented by Epstein as Genesis) is the guiding spirit of woman, and consciously or unconsciously, moulds all her feelings, emotions, and actions, and the giving up of the power to reproduce the race is to most women a definite act of renunciation. The husband ought to be consulted. Legally, indeed, he has no right either to compel his wife to have an operation or to prevent her. Actually, he is entitled to a full explanation. In some of the cases of this series, patients who have lost their sex feelings have said: "But I have a good husband, and he really doesn't care; he is so pleased to see me well." The family doctor must be in accord; it is wrong to remove both ovaries if he disapproves. The convalescence after hysterectomy is necessarily longer than after the average operation, and the patient more open to the influence and suggestions of the family doctor; it is therefore more than usually important that the operation should have his full approval.

Good operative technique and post-operative care assist in eliminating subsequent neurosis. Patients should be warned that it may take a year or more for them to reap the full benefit of the operation, and that for a time they will suffer from menopausal symptoms. Convalescence should be carefully graduated up to complete restoration

to health. Patients are often told not to "do too much." This elusive phrase really means that they must not incur more fatigue in any one day than they can completely recover from by virtue of the rest of the succeeding night—an important principle in any convalescence. The cutting down of social duties, the abolition of late nights, a period of complete rest lying down in the middle of the day, and a change of air facilitate an early cure. Here are some types of the neurotic condition that may follow hysterectomy.

Case 1.—A married woman, aged 49, a midwife in active practice, had a hysterectomy for menopausal haemorrhage. A few months later she was readmitted to hospital, and a very careful house-surgeon investigated her case with much detail. She remained seven weeks without benefit. At the end of a year she was a chronic invalid. One day her doctor said to her: "Mrs. A, I have had more than enough of this. I am satisfied you have nothing at all wrong with you. You have had your surgeon and myself at your tail for long enough. I shall attend you no more unless you are really ill. Get another doctor if you like. My advice is 'Get along, and do your work. Good-bye.'" From that day, now ten years ago, she has worked and is in good health.

Case 2.—A single woman, aged 26, had hysterectomy performed for an extreme degree of anaemia due to menorrhagia, which was threatening her life. She recovered slowly, but remained dull, listless, and apathetic. A few years after, her sister had a child, and with her interest in her sister's child she lost her neurosis and regained her youth.

Case 3.—A doctor's wife, aged 39, had suffered from severe dysmenorrhoea and menorrhagia for years, and became so ill that her husband was afraid, and not without reason, that she would not survive another period. After hysterectomy, for fibroid, with removal of the appendages, she gradually recovered, despite occasional attacks of tonsillitis, and mild rheumatic symptoms. Every three months she was able to recognize her periods from the old depression and malaise, and an exacerbation of flushings and sweatings. Several ovarian extracts had been tried without benefit. Four years after operation ovarian epilettes (Parke, Davis and Co.) were given, and at once improved her nervous tone and general health, and the old periods became unrecognizable.

Some years ago I was invited to lecture to the Chartered Society of Massage and Medical Gymnastics on "hysterectomy." This choice of subject surprised me. I was told that so many cases of hysterectomy were referred to them for massage that they wanted to know the surgeon's point of view; they stated they believed that a certain degree of neurosis was an inevitable sequel of all abdominal operations, excepting perhaps an uncomplicated appendicectomy. Such a criticism ought to stress the methods of preventing neurosis underlined in this paper. It must be borne in mind, however, that neurosis, and even mental upset, may exist apart from operation or at the menopause.

Four cases of mental upset of varying degrees occurred in this series. One began six months before operation, which was in itself beneficial. Another patient had mucous colitis and fits before operation, and remained somewhat neurotic. A third developed fainting attacks with loss of consciousness at rare intervals after an operation otherwise successful. The fourth developed an anxiety neurosis two or three months after operation; this is still improving after eight years. These last three cases are classed above as in indifferent health.

LEUCORRHOEA, BACKACHE, FREQUENT MICTURITION

The high cure ratio of these common and very distressing symptoms was remarkable. Leucorrhoea was cured in forty-five out of fifty cases (90 per cent.); backache cured in thirty and relieved in three out of thirty-seven cases (90 per cent.); frequency of micturition cured in twenty-eight out of thirty cases (93 per cent.). I have

no data by which to interpret this curiously high percentage of cure. It is interesting to note that in the treatment of the "gynaecological" backache Young¹ finds that repair of the torn cervix is very effective, whereas in nearly all these cases the cervix was left.

ADDITIONAL NOTES

Several patients thought they could identify the time of their periods for some months after operation. One stated she lost blood from her nose for many months at intervals corresponding to her periods. An occasional case had gall-stones, which were not removed at the same time. Upper vaginal prolapse was cured by the operation. Some patients had previously had operations for prolapse; others had subsequent operation for prolapse of the vaginal walls. Only one case required a laparotomy consequent on the hysterectomy—namely, for acute obstruction, after eight years. The old notes were investigated, and it was found that she had some vomiting and distension for a few days after the original operation; she had never been really well since. At the second operation there were adhesions of the small intestine in the pelvis. Such a result, accruing no doubt from a post-operative ooze, emphasizes the need for a careful technique. This patient's troublesome symptoms completely disappeared after her second operation. The absence of any complaint about constipation was remarkable. Only in two or three cases was it complained of, and in each of these adhesions of the sigmoid had been noted as present at the time of operation. There was no complaint of menopausal rheumatism; neither was there any mention of symptoms of atrophic vaginitis.

MORTALITY, ETC.

For the sake of completeness the records of the remaining eighty-three cases were investigated. There were three deaths, one of which was due to the anaesthetic, giving a death rate of three in 198, or 1.5 per cent. These remaining cases included eleven of malignant disease of the body or cervix, and one rare condition, a large angioma of the body of the uterus.

SUMMARY

1. An analysis is given of the after-histories of 112 cases of hysterectomy.
2. In the light of the facts as ascertained controversial questions such as whether ovaries should be removed or left are reviewed.
3. The effects of hysterectomy as regards obesity and sex feelings and menopausal phenomena are investigated.
4. The factors that lead to a uniformly successful result are discussed.
5. The mortality of the total series of 198 consecutive cases of hysterectomy was three, or 1.5 per cent.

I wish to express my thanks to my house-surgeons, especially Mr. Richard Saunders, for valuable assistance.

Food Investigation Special Report No. 43, on the storage of meat in small refrigerators, has been issued by the Department of Scientific and Industrial Research (H.M. Stationery Office, 9d.). This explains why meat sometimes fails to keep for a reasonable time in small refrigerators, such as butchers commonly use. While a refrigerator may be sometimes misused by overloading or otherwise, the most frequent cause of wastage is heavy infection of the meat by micro-organisms. The report shows how this infection comes about, and how it can be avoided.

PERNICIOUS ANAEMIA IN AN ASIATIC

BY

ERIC C. SPAAR, B.A., M.D., M.R.C.P.

PHYSICIAN, GENERAL HOSPITAL, COLOMBO

Pernicious anaemia has hitherto been unknown in the Asiatic. I have certainly not been able to find any reference to any such case in the literature, nor have I met with a single such instance of the disease before. It is remarkable, on the other hand, that another blood disease, leukaemia, is by no means uncommon. In my own wards no fewer than half a dozen cases of the latter were seen during the course of last year. This opinion is also shared by Dr. Brunel Hawes, professor of medicine at the Singapore School of Medicine, who saw my patient on a recent visit of his to this hospital.

CASE RECORD

The patient, a female Sinhalese, aged 55, was admitted to the General Hospital, Colombo, under my care on July 17th last. She answered to the three great criteria necessary for an accurate diagnosis of true Addisonian anaemia—namely, (1) the absence of free HCl in the stomach contents of every specimen of a fractional test meal, (2) a positive indirect van den Bergh reaction, and (3) megalocytosis with a raised colour index.

The Price-Jones curve, as furnished me by the laboratory attached to this institution, is given below. It shows the definite shift to the right, and is characteristic.

CHART 1.

History and Symptomatology

The symptoms for which the patient sought admission to hospital were: dyspnoea of two years' duration, with palpitation on the slightest exertion, a feeling of lassitude, headache, sleeplessness, and loss of appetite. The onset of her illness had further been marked by vomiting and discomfort in the abdomen. Latterly the sense of extreme weakness and exhaustion, with a progressive pallor of her tongue and conjunctivae, were so marked that her life was despaired of, and she was brought by her brother for admission to my ward as a last resource. Inquiry, however, revealed the fact that there had been a previous admission to hospital nine months before for the same symptoms, and that she had on that occasion been given a course of six intravenous injections of neosalvarsan, because of a positive Wassermann reaction in her blood. She denied any possibility of a venereal taint, however. Her blood, on examination, gave an anti-complementary result at first, but on being retested a month later, without the administration of any arsenical medication, proved to be definitely negative to the Wassermann test.

Physical and Laboratory Findings

She was a fairly well nourished subject, although she stated that there had been some loss of weight. The dark-complexioned skin was of a lemon-olive tint. The tongue was large, flabby, and absolutely bloodless. She was practically edentulous, with only half a dozen septic stumps. The conjunctivae were colourless. The heart was slightly dilated, with a soft, blowing systolic murmur at the apex; the lungs were healthy. The liver was not enlarged; the spleen was just palpable. In spite of the severe grade of anaemia there was, as will be seen presently, no indication whatever of any involvement of the nervous system. Her blood count on the third day of her stay in hospital was: red blood cells, 800,000; white blood cells, 3,800; haemoglobin percentage, 18; colour index, 1.1. Differential count, polymorphonuclears 48 per cent., lymphocytes 52 per cent.

No nucleated reds were seen in the blood film, but there was marked poikilocytosis and anisocytosis, as well as polychromatophilia. Malarial parasites were not found in the blood, nor was there a history of past infection. The stools were consistently negative to the ova of the ankylostome. Her temperature was occasionally febrile during the first three weeks of her stay in hospital. Pulse 76, of poor volume and tension.

Treatment and Progress

Ten days later, on the thirteenth day of her stay, the blood count was: red blood cells, 500,000; haemoglobin percentage 10.

No reticulocytes were seen in the blood film stained by cresyl-blue. The only treatment she had had in the interval was a mixture of ferri et ammon. cit., and half a dozen injections of caedylate of soda. Treatment for pernicious anaemia was begun on the same day—that is, on the thirteenth day after admission, with intravenous injections of liver extract P.A.F. On the fifth day following, the reticulocytes had risen to 6.1 per cent. of the total red blood cells. This was the peak of the rise—a poor response indeed. By the end of the ninth week of treatment these were no longer present, however, none being seen in a count of 1,000 cells. The number of erythrocytes and the percentage of haemoglobin showed, on the other hand, a steady rise throughout the period of observation. Her diet consisted of rice, fresh vegetables, beef, and fruit.

The treatment adopted and its effect on her blood picture is shown in the table below.

Date	R.B.C. in millions	Hb Per. centage	Reticulo-cyte Per. centage	Treatment
19/7/33	800,000	18	Nil	Ferri et ammon. cit. mixt. orally; six injections caedylate of soda simultaneously
22/7/33	500,000	10	Nil	Six injections hepatex P.A.F. intravenously
3/8/33	1,320,000	30	6.1	Hepatex with iron orally for ten days—that is, the equivalent of 1,000 grains daily of fresh liver
12/8/33	1,400,000	38	5.0	Six injections hepatex P.A.F. intravenously
18/8/33	1,500,000	40	3.0	Ten intramuscular injections of campolou; septic stumps extracted from jaws
28/8/33	2,160,000	52	3.5	Five intramuscular injections of campolou; hepatex with iron by mouth—the equivalent of 1,000 grains daily
2/9/33	2,400,000	53	1.0	Three intramuscular injections of campolou and hepatex with iron by mouth as before
10/9/33	3,000,000	60	0.6	Three intravenous injections of hepatex P.A.F., as well as hepatex with iron by mouth in the usual dosage
17/9/33	3,000,000	60	0.6	Six intramuscular injections of campolou and hepatex with iron orally
24/9/33	*3,200,000	60	0.8	Three intramuscular injections of campolou and hepatex with iron by mouth, the equivalent of 666 grains daily
1/10/33	3,600,000	65	Nil in 1,000 R.B.C.	Hepatex by mouth, the equivalent of 165 grains daily

* The colour index was below 1 for the first time.

The patient left hospital three days later, having gained 20 lb. in weight during the last month of her stay.

Chart 2 shows the definite progress in the condition of the patient with no relapse for the period of nine and a half weeks during which she was treated for pernicious anaemia.

CHART 2.

DISCUSSION

The maintenance dose necessary to keep her well could not be correctly determined, as the patient left hospital a few days later after a stay of eleven weeks. She was then looking quite fit, felt strong and well, and had gained considerably in weight, as already mentioned. Her tongue

was of a normal rose tint. She was asked to continue taking a dessertful of hepatex twice a day, which was the quantity she had been given during the last week of her stay, without any setback.

The most noteworthy feature of the case was, however, the slow response to treatment. While it is held that an active preparation of liver extract will induce a rise in the reticulocyte percentage to a maximum of between 30 and 70 per cent. within seven to twelve days of commencing treatment, the peak in her case corresponded to an increase of only 6.1, while it required intensive treatment for a little over two months to bring her blood picture to anything like a satisfactory condition.

The idea naturally arises in one's mind that preparations of liver extract, whether for enteral or parenteral administration, are prone to deteriorate in the Tropics to a great extent.

The positive Wassermann reaction of the patient's blood on her first admission to hospital was evidently a false positive, due to some unknown factor in the blood, as suggested by L. S. P. Davidson, who has noticed such a false positive in several cases of grave anaemia.

Clinical Memoranda

A CASE OF CONVULSIONS AFTER ETHER ANAESTHESIA

The following is a case of ether convulsions occurring in this hospital, which I feel is worthy of record, as it shows a further possible line of treatment.

CASE HISTORY

A girl aged 11 was admitted to the Queen's Hospital, Birmingham, on October 1st, 1933. She had been ill for four days with abdominal pain, vomiting, and sore throat. The pain commenced in the epigastrium and localized in the right iliac fossa, while it was colicky in nature. There was no evidence of any epileptic tendency in the patient's personal or family history. When examined she was obviously very toxic, the throat being inflamed and the tongue dirty. The temperature was 103° F., the pulse rate 120, and the respiration rate 25. The whole abdomen was rigid, and the tenderness was most marked over McBurney's point.

After a hypodermic injection of 1/75 grain of atropine she was anaesthetized with ethyl chloride, followed by open ether. The induction, which commenced at 3.55 p.m., was quiet and the anaesthetic satisfactory, the patient being kept in the middle of the third stage throughout the operation. Pelvic peritonitis was present and the appendix was retrocaecal, while the wall of the caecum around the appendix base was swollen, oedematous, and in a state of cellulitis. Some of the mesenteric glands were enlarged. At 4.30 p.m., just as the peritoneum had been closed and the anaesthetic withdrawn, she began to develop convulsions. These commenced in the right foot and leg, rapidly becoming generalized. The face became cyanosed and the conjunctivae congested. Her head was raised and oxygen was administered. It was evident that all peripheral stimulation, such as even the needle-pricks as the surgeon was sewing up, started convulsions. The operation was therefore concluded as rapidly as possible, and all interference produced by active attempts to resuscitate the patient was stopped, even the stream of oxygen being discontinued. Then, within a few minutes, the convulsions became less violent, and soon ceased. No further fits occurred, and she made an uneventful recovery.

The main feature of this case appears to be the almost immediate cessation of the convulsions on suspension of

active treatment, and this suggests a course which can be further tried in other cases such as this.

In conclusion, I should like to thank Mr. Hugh Donovan, F.R.C.S., under whose care this patient was, for permission to publish these notes.

D. MASTERS BROWN, M.B., Ch.B.,
House-Surgeon, Queen's Hospital,
Birmingham.

MYOMA OF TRANSVERSE COLON

The following case may be of interest to readers on account of the rather rare tumour that was found on laparotomy.

A man, aged 54, was being measured for a truss when it was seen that he had a large lump in the abdomen. The patient had noticed an increase in his abdominal girth during the previous five or six months, but as he had suffered no symptoms he had not thought it necessary to apply for advice.

On examination a large, fairly well defined mass was felt in the centre of the abdomen, partly occupying the epigastric and umbilical regions. It was not freely movable, and remained fixed on respiration. It was dull on percussion, and felt very solid, so much so that at first it was thought to be an enlarged spleen, but the blood picture was normal.

Laparotomy was performed on August 16th, 1933. A tumour surrounding the middle of the transverse colon was found, embedded in omentum, with coils of small bowel adherent to it. These latter were easily separated, and the tumour, with the enclosed piece of colon, was removed. Recovery was uninterrupted.

The pathologist's report described the specimen as a large lobulated myoma measuring 7½ by 5½ by 5 inches. A section made longitudinally through the attached colon shows that the tumour arises from the circular muscular coat of the bowel. Microscopical section shows the growth to be a leiomyoma. It consists of interlacing fasciculi of smooth muscle cells. There is no suggestion of any malignant change.

I am indebted to Dr. Lawrence, pathologist at the Museum of the Royal College of Surgeons, where the specimen is being preserved, for his report, of which the above is an extract.

G. J. GRIFFITHS, M.B., F.R.C.S.,
Assistant Surgeon, Bedford County
Hospital.

Reviews

THE CAMPAIGN AGAINST SYPHILIS

"O fortunatam natam, me consule, Romani," wrote Cicero; substitute Dr. LOUIS SPILLMANN for Cicero and Nancy for Rome and the reason seems clear for the publication of "The Evolution of the Struggle against Syphilis—A Review of Twenty-five Years."¹ In his preface the author states that he proposes to demonstrate methods adopted as suggested by the march of events and the evolution of ideas, and describe the present position of affairs; his main contentions are that the campaign should be an epidemiological one, and that it is necessary to seek out the source of every infection and deal with it.

Commencing with a historical survey dating from 1880, he shows how inadequate was the accommodation for dealing with the problem when he took charge in 1907. He at once set to work to improve matters, more particularly by increasing the accommodation and by taking steps to see that all infected prostitutes were hospitalized. During the next few years he noted a remarkable fact—namely, that, whereas the numbers of female infections fell, the male ones rose; this was explained by the great increase in the number of "clandestine" prostitutes. In 1914 the war intervened, and the author spent the next few years in Lorraine with the 8th Army. Here cases were divided into three classes: (1) old cases under treatment; (2) established cases; (3) recently infected cases. The first were treated when out of the line, the second and third were sent to special hospitals, treated intensively, and returned to their units as quickly as possible. A brochure was issued to the troops pointing out that syphilis is a grave disease, and showing how it is caught, how recognized, how avoided, and how treated.

After the war Dr. Spillmann took up the threads again at Nancy, and demanded an up-to-date clinic; he insisted on the importance of early diagnosis of syphilis and the necessity of warning the public by a propaganda campaign. For this are needed the education, sexual and anti-venereal, of the young adult, and prophylaxis among workers. For the public campaign a conference was held at Nancy in 1928, where the author set out his views. Propaganda, he said, can take the form of lectures, articles in the Press, posters, the theatre and film, and wireless. A big part in the struggle should be played by the "Social Service," a body of women akin to almoners in this country. The ladies constituting this body in the region of Nancy seem to have been remarkably competent, for defaulting "is rare" following a letter of reminder, and a visit to the patient is "nearly always successful." Great stress is laid on tracing the source of all infections and inducing the offender to submit to treatment. A strong case is made out for pre-nuptial certificates of freedom from venereal diseases, and it is pointed out that these have worked well in Sweden, the marriage rate having actually gone up following their institution, not down, as the opponents of the measure anticipated. Without this system congenital syphilis may be expected to continue to kill thousands annually.

The technical organization in the district is set out in detail, including a central dispensary and general sub-dispensaries; the author's view is that it is better not to have *ad hoc* institutions, and he deprecates the use of the word "venereal": syphilis is not by any means necessarily venereally acquired, nor need it carry any moral stigma. The working of the dispensaries is de-

scribed in detail, and various and complicated "case cards" are explained; very rightly stress is laid on the use of the dark-ground microscope wherever applicable in order that the diagnosis may be made at the earliest possible moment. The relations between the clinics and private doctors present difficulties—and always will; the clinics are primarily for the indigent, but those who can pay do so according to a scale of charges. Summing up, the author insists that it must be recognized that syphilis has changed—we no longer see the old destructive lesions. New methods of diagnosis and treatment are now available, and full use must be made of them; in particular, students should receive more instruction in venereal diseases, and syphilis should be treated by a specialist. Propaganda should be educative and old prejudices done away with; the disease should be treated more on the lines of the infectious fevers, but agreement as to whether it should be made notifiable is not likely to be reached. More money is needed; if as much were spent on syphilis as on tuberculosis or cancer, far more effective results would be obtained.

Though the book is written in a rather flamboyant style and apparently for the self-glorification of the author, it must be admitted that it contains much that is sound, if not new, and that he has made a sincere attempt to tackle a difficult problem. If the "Social Service" is all that is claimed for it, this should be the biggest individual factor in lessening the ravages of syphilis, though how it can deal effectively with the modern "clandestine prostitute" or "amateur" we find it hard to understand. A list of forty-nine articles by the same author, published between 1908 and 1933, is appended. This book will not make much appeal to English readers.

HISTORY OF DISEASES

The study of the history of medicine has been enthusiastically taken up of late years in English-speaking countries in particular, and the latest evidence of interest in the subject is to be seen in the publication, *A Short History of Some Common Diseases*,² by divers authors, which Dr. W. R. BERT has edited. In his brief preface the editor states that these essays are intended mainly for students and practitioners of medicine, and possibly also for patients. Without this announcement we should have been in some doubt, for, although the articles are expressed for the most part in technical language, there is a popular feeling about them, and they lack the terminological pedantry of the monograph or textbook. But these remarks must not be taken to apply to all the contributions in equal degree, for some of them may be described as concise statements of all that is known of the subjects discussed.

"The acute infectious diseases," the subject entrusted to Sir John Broadbent, is obviously too large a one to be fully dealt with in a short essay, and he has wisely confined himself to a sketch of the history of the best-known acute infections. The regius professor of surgery in the University of Edinburgh traces the history of tuberculosis from that usual source, Hippocrates, until the present day, and the efforts made in this country to combat the scourge. There is a note of doubt in his closing paragraph, which leads one to think that he is not sure that we are getting our money's worth for the vast sums expended by public authority. Sir D'Arcy Power writes with his usual mastery on the venereal diseases, but hardly succeeds in lifting the veil over their early history, before Columbus discovered the West Indies.

² *A Short History of Some Common Diseases* Edited by W. R. BERT, M.R.C.S., L.R.C.P. By divers authors. Oxford Medical Publications. London: H. Milford, Oxford University Press, 1934. (Pp. 211. 10s. 6d. net.)

¹ *L'Évolution de la Lutte contre la Syphilis*. Par L. SPILLMANN. Paris: Masson et Cie. 1933. (Pp. 292; illustrated. 30 fr.)

Probably it never will be lifted completely. Sir D'Arcy is one of those who think that syphilis was introduced to Europe by the sailors of Columbus, on their return from his second voyage. Some American authorities are still unconvinced. The question whether its origin be European or transatlantic is now of purely academic interest compared to the tremendous fact of the discovery of the spirillum and of methods of radical treatment, which, if generally carried out, might eradicate the disease.

Dr. E. M. Brockbank's paper on pneumonia and that of Dr. F. J. Poynton on rheumatism are masterly. Dr. Leonard Findlay writes on rickets, and seems inclined to give far more credit to Whistler and far less to Glisson than has been done by Sir Norman Moore and others. Fate has been kind to us in suppressing Whistler's ill-starred attempt to designate the disease *paedospianchnosteocases*.—Better far that it should long have been known as the English disease! In the seven pages devoted to Bright's disease Professor J. A. Nixon of Bristol has contrived to give not only a clear account of the history of nephritis, but also a charming biographical sketch of his eponymous hero.* Bright may be said to have been an Admirable Crichton of medicine. He excelled in many lines, and despite bitter opposition at first, he achieved success when quite young. The subject of Dr. R. O. Moon's article, heart disease, is too technical to be understood by non-medical readers, but his facts are clearly stated. So little has been really known about the pathology and physiology of the heart, even after Harvey, until recent years, that there is not much to be said of its history. Of epilepsy, on the other hand, the history of symptoms goes back for centuries, and the New Testament provides a graphic description of a typical seizure. Despite the long history of the disease and of its treatment, there has been little progress made in its cure, but Dr. James Collier gives us a fascinating account of past studies and treatment. Dr. John D. Comrie's paper on arthritis is full of interest and important historical facts.

The editor of the book gives a lively account of appendicitis and of King Edward's obstinacy and final surrender to the advice of his medical attendants. We have always felt that the great weight of responsibility at the operation rested on the anaesthetist, the late Sir Frederic Hewitt. Mr. Harold Burrows gives us a succinct account of the present position of research into malignant disease and its treatment. The surgery of tonsils and adenoids has so short a history that Mr. Lionel Collidge has little opportunity for picturesque writing, but he gives a clear description of "T. and A." and their treatment.

INCIDENTS FROM GENERAL PRACTICE

All doctors who can look back on twenty years or so of general practice must have many tales to tell and experiences worth recording. Only a few such practitioners, however, have enough inclination, leisure, liveliness of memory, and literary ability to allow of these experiences being related acceptably in print. The excuse given by Dr. ERNEST PARKER for writing his book *In and Out of My Consulting Room*—that it afforded him occupation during convalescence and so relieved his monotony—can scarcely be accepted as a sufficient justification in itself; but the book is so good that he might have spared himself the apology. Though not free here and there from some slight faults of literary style, most of the incidents he narrates are not only interesting in themselves but are told with considerable ability and real effectiveness. They deal entirely with the human side of medical practice; they are not designed to add to scientific

or clinical knowledge; nor, except quite casually in one or two cases, do they convey any special hints for actual practice, though they manifest the spirit in which a successful practice should be conducted, and show throughout evidence of commendable skill, care, attention, hard work, kindness, and generosity in the author. They are just short stories or mere anecdotes of events which occurred in his own experience, and all of which he asserts to be true. Some of those among his "pot-pourri" were perhaps scarcely worth recording, and perhaps one or two had better not have been recorded. A few carry with them a certain definite flavour of familiarity, but then, as Dr. Parker himself declares, similar experiences must have befallen many general medical practitioners! The book can be commended as an admirable refresher for idle moments not without some more serious influences, but it will doubtless be most fully appreciated by medical practitioners themselves, by their families, by nurses, and by others who in their daily life are more or less closely associated with the circumstances of a general practitioner's work.

ATLAS OF PATHOLOGICAL ANATOMY

Through the liberality of the municipal authorities of Amsterdam the pathological department of the University has for some years been able to employ artists to execute drawings of pathological specimens. From this large collection Professor DE VRIES has now chosen a number of the more interesting drawings and published them in a handsome folio *Atlas of Selected Cases of Pathological Anatomy*.† The plates, seventy-three in number, are almost all coloured and are beautifully executed; they are accompanied by descriptions of the specimens, their clinical histories, and post-mortem appearances, concisely written in the manner adopted in our museum catalogues. The text is written in English.

In making his selection Professor De Vries has endeavoured to illustrate lesions in most of the regions and organs of the body, and he has chosen specimens which are either specially characteristic, or uncommon, or of which good drawings do not exist in available literature. Mere pathological curiosities have been excluded. Among the rarer specimens, such as are likely to be found in very few museums and good figures of which will therefore be valued by pathologists, may be mentioned the primary spindle-celled sarcoma of the veins figured in Plates 16 and 17. The patient from whom this specimen was taken had had for about two years a number of small, rather tender nodules and strands on the inner side of her left leg. A diagnosis of thrombosed varicose veins was made, but as the involved area grew operation was decided on, when the nature of the lesion was disclosed and amputation was performed. The specimen consists of a network of solid cords with localized thickenings at intervals, producing a moniliform appearance. Two years later a nodule appeared on the hip, followed by haematuria and the development of a large tumour in the right hypochondrium; the right eye was nearly blind, and the supraclavicular glands were enlarged. Death occurred about four years after the amputation. Other noteworthy lesions illustrated are chronic yellow atrophy of the liver, neurocytoma of the liver (Pepper's type), diffuse melanosis of the spinal pia-arachnoid, and tuberculosis of the inferior cervical sympathetic ganglion.

In the publication of the *Atlas* generous assistance was afforded by the curators of the Dekker Fund and the Amsterdam University Union. Professor De Vries is so to be congratulated on the success of his undertaking.

* *In and Out of My Consulting Room*. By Dr. Ernest Parker. Leicester: Edgar Buckus. 1933. (Pp. 240. 7s. 6d.)

† *Atlas of Selected Cases of Pathological Anatomy*. By Professor W. M. De Vries. Amsterdam: J. H. de Bussy, Ltd. 1933. (25 Dutch guilders.)

ORGANIC CHEMISTRY

SHERWOOD TAYLOR's textbook of *Organic Chemistry*³ is professedly written with a special regard to the requirements of medical students; it is, nevertheless, a fairly comprehensive treatise on the subject. Experience of modern textbooks on organic chemistry leaves with the reader an impression either of a confused medley of unmeaning formulae or (when the treatment is more elaborate) of a mass of descriptive detail that obscures the way to a grasp of principles. Taylor's work is largely free from these defects. It describes in clear language exactly what the student wants to know, and adds only such supplementary information as will serve to connect the facts of organic chemistry with general knowledge. Thus it is stated that adipic acid is used in the preparation of baking powder. Information of this kind serves the double purpose of adding interest to the subject and of providing a basis of mnemonic aid.

A notable merit of the book is the fact that the treatment is thoroughly modern. This applies not only to sugars and matters which have received an unusual share of recent attention, but also to the more ordinary organic compounds. A set of questions is given at the conclusion of each chapter which are well calculated to arrest the student's attention, and to guide him to a grasp of the principles of the subject. The text is arranged in numbered paragraphs, and references are frequently inserted in the text calling attention to the number of another paragraph which furnishes information supplementary to the matter discussed. This arrangement will prove of much help towards a connected and coherent understanding. The volume is well indexed, and is thus no less serviceable as a work of reference than as a student's textbook.

Notes on Books

In his preface to the fourteenth edition of Bruce and Dilling's *Materia Medica and Therapeutics*⁴ Professor WALTER DILLING recalls the death of Dr. J. Mitchell Bruce on July 11th, 1929. "He was a courteous and esteemed physician, a skilful therapist, and a beloved colleague." It is now just on fifty years since Mitchell Bruce first launched this valuable little book, and its success may be judged from the fact that thirty-five editions and reprintings have been called for. Publication of the *British Pharmacopœia* (1932) has afforded Professor Dilling one more opportunity to revise the work completely, and the main part of the text has been reset in larger type. The "pure materia medica" is now squeezed into smaller compass, and the work as a whole has been recast so as to drive into the student's mind the logical relations between pharmacological action and therapeutic use. The official remedies of the B.P. are adequately discussed, and many drugs and methods which are not yet official but which promise to advance therapeutics are considered. The section on general therapeutics has been brought into line with modern pharmacological knowledge.

Professor R. D. RUDOLF's *Notes on the Medical Treatment of Disease for Students and Young Practitioners of Medicine*⁵ first appeared in 1921, and after the manner of textbooks has grown in length, in this instance by about one hundred pages. It has been carefully revised, and changes necessitated by the new edition of the *British*

Pharmacopœia duly made. As was pointed out in the review of the original edition in these columns, this work happily blends ancient with modern knowledge, as judged by a wise experience; thus Hippocrates and Galen are not forgotten, and the liver and stomach extract treatments, of Minot and Wilkinson, of Addisonian anaemia, whereby its former and familiar adjective "pernicious" has been made obsolete, find a place. The same is true about the treatment of Addison's disease by adrenal cortex extract, a complaint being not unnaturally registered about its expense. Many will cordially agree with the sound and Waltonian statement in connexion with the treatment of chronic heart disease that "fly-fishing is a gentle and pleasurable exercise for those who are fond of angling," and be loath to limit its employment in other directions, any more than this work should be restricted to young practitioners of medicine.

Dr. IRENE CLARK has written a very useful book⁶ on bacteriology and pathology for nurses. It should prove particularly useful to sister tutors, though it might be well to warn them that the author goes a little more fully into some branches of pathology than is expected in their examination syllabus. The third section, dealing with practical methods, is very well arranged. The only criticism we have to suggest is that the book would be more readable if it contained fewer colons and semi-colons and more full stops. Scientific facts are much more easily apprehended if the sentences are short. Proper punctuation and a little more respect for English grammar would greatly improve this otherwise admirable book.

The latest volume in the Notable British Trials Series is devoted to the *Trial of Benjamin Kueteles*,⁷ which in point of fact took place not in Britain but in Ashanti, though the appeal was heard in London by the Judicial Committee of the Privy Council. Dr. Knowles, medical officer for the Beckwai District, was charged with the murder of his wife by shooting her in their bungalow; he was tried and found guilty, and sentenced to death by the acting circuit judge of Ashanti, sitting at Kumasi without a jury. The sentence was commuted by the Governor to one of imprisonment for life, but after argument before the Judicial Committee in London the conviction was quashed some twelve months later. The main outline of the case must still be fresh in a good many memories. Mr. ALBERT LIECK's strongest justification for reviving a wretched story is that a great principle of law was involved—the right to trial by jury. "Not lightly is the conclusion to be reached that a British subject in British lands is lawfully triable for his life without a jury, and debarred from the assistance of counsel."

The monograph on *Heine-Medin's Disease*⁸ by Dr. LUIGI CERZA, assistant to the Institute of Clinical Paediatrics at Naples, gives a concise and up-to-date account of the various aspects of the disease which is generally known in this country as infantile paralysis or acute poliomyelitis, based on a study of the literature and personal observations of 297 cases treated at the Naples Institute during the quinquennium 1928-32. A bibliography of recent literature is appended.

Messrs. Faber and Faber have now issued a fourteenth edition of *The Nurse's Dictionary* (3s. net), revised by Miss FLORENCE TAYLOR of Guy's Hospital, which brings this popular little reference book into its 464th thousand. *The Midwife's Dictionary and Encyclopaedia*, revised by Miss GLADYS B. CARTER of the Midwives' Institute (same publishers, 3s. 6d. net), is planned on parallel lines, and should prove equally useful to those for whom it is intended. Both dictionaries are of pocket-book size (5 in. by 3½ in.), and the general arrangement and typography are identical.

Preparations and Appliances

A URETERIC MEATOTOME

Mr. H. P. MURBURY-WHITE, F.R.C.S. (London, W.1), writes:

The electrode shown in the figure has been constructed for use with a high-frequency cutting current, and is employed trans-cystoscopically. After the instrument has been passed through the cystoscope, and its tip inserted into the ureteric orifice, a button is pressed at the outer end; a loop of wire, 1/2 cm. in length, is thus made to project laterally for about 2 mm. near the point of the instrument. This loop is the cutting part of the electrode, and is brought into contact with the upper margin of the ureteric orifice. On pressing the foot switch it is easy to assure that the resulting slit in the wall of the ureter only cuts the portion required, the rest of the ureter being adequately protected by the insulating material. The instrument has been of great service in assisting the passage of ureteric calculi impacted in the pelvic portion of the ureter. It is made by the Genito-Urinary Manufacturing Co., Ltd., 28A, Devonshire Street, W.1.

TREATMENT OF PERSISTENT EPISTAXIS

Mr. A. TUMARKIN, F.R.C.S. (Liverpool), writes:

Epistaxis, though very alarming to both patient and onlookers, is rarely serious, and usually easily controlled and cured; on the other hand, desperately dangerous and even fatal cases have been reported. The following, although never alarming, was quite the most obstinate case I have ever encountered.

Mrs. M. H. began with epistaxis in 1899, as a girl of 14 years, and trailed round endlessly from private doctors to hospitals and back again. She was naturally cauterized endless times, and was given various lubricants. Later, "bits of bone were snipped off," and early in 1931 her septum was resected; this gave her freedom for a month, but then the condition recurred. Her nose used to fill with sanguineous crusts, and she bled regularly two or three times a week, and every few weeks had a really big loss. Both sides bled, but the left was worse by far. I saw her early in February, 1932, and after removing the crusts found the septum generally engorged and velvety, but with no outstanding vessels worth cauterizing. In despair I decided to use radium, and in all she had the following applications.

February, 1932.—One 3 mg. needle, 8 mm. screenage, left nostril, twenty-four hours.

July, 1932.—Three 1 mg. needles, 8 mm. screenage, right nostril, forty hours.

November, 1932.—Two 1 mg. needles, 8 mm. screenage, left nostril, forty-eight hours.

June, 1933.—Two 1 mg. needles, 6 mm. screenage, left nostril, forty-eight hours.

The patient was very enthusiastic about the results. Almost at once the left side dried up, and she insisted that I should go on to the right. I deferred this until July, fearing a delayed reaction in the cartilage. After the July treatment the right side stopped bleeding but the left recommenced, and so in November I gave another treatment as indicated. This again stopped the bleeding, but in June, 1933, as there were occasional trivial losses, I gave her a final treatment. Since then she has had no further haemorrhage. The nose, however, is still liable to fill up with crusts, and in this connection I would draw attention to a lotion which I have found to be by far the best application: fel bovinum 2 per cent., sodii bicarb. 5 per cent., glycerin 20 per cent., aqua ad 100 per cent.

The classical treatment of epistaxis—namely, the application of the cautery or of caustics to the "bleeding area"—

has always seemed to me open to objections. Faced with a bleeding patient, one's first thought is to arrest haemorrhage; this done, one looks at "Kiesselbach's area" and wonders where to begin. I have so often seen these patients with scars, crusts, ulceration, and even perforation in the area of Little (or Kiesselbach), that some time ago I began to wonder whether some more rational and less destructive line of treatment could be evolved. The more so as this crusting is so irritating, and, especially in children, sets up the habit of nose-picking, which in its turn produces the dreaded epistaxis once more. Little's area is supplied (see diagram) from above and behind by the septal branches of the sphenopalatine artery and from below by the septal branch of the coronary artery. Possibly also the descending or anterior palatine may send a branch up through Stenson's foramen, but this is of no importance. It seems to me far preferable to attack these vessels, and this has proved eminently satisfactory. Often it is possible to make out a largish vessel entering from above or behind, but certainly in a very considerable proportion of cases one can discover a distinct vessel or leash of vessels below. Usually these run across the floor of the vestibule in a ridge actually in the muco-cutaneous junction, but sometimes one or more vessels run parallel about 1/4 inch posteriorly. They are especially distinct in the cases where a horizontal spur is present.

Treatment should be directed in the first instance to these latter vessels. I have found the chromic bead surprisingly efficacious. It is quite painless; even children tolerate it without cocaine. If this is insufficient to control the haemorrhage, one attacks the postero-superior vessels at a later date. For this I use a special cautery point and produce a more or less continuous trench, as in the diagram.

This is placed well away from the area where "spontaneous" perforation of the septum is liable to occur. It heals rapidly, and does not form troublesome crusts. This line of treatment has enabled me, almost entirely, to dispense with the old method of treating this very troublesome condition.

THE "DAVON" SUPER-MICROSCOPE

F. Davidson and Co. (143-149, Great Portland Street, W.1) announce the construction of a new microscope for the rapid examination of uncovered slides at a fixed magnification of $\times 1,000$ (Bacteriological Outfit No. D.9). The apparatus, which comprises a horizontally mounted microscope, employing eyepiece, "collector," and primary and secondary objective, enables full magnification to be obtained with a 1/6 inch instead of a 1/12 inch lens. It is compact, easy to operate, and gives excellent results with stained blood or pus smears.

APPLE POWDER

"Aploma" is stated by the vendors to be a specially prepared apple powder, which they recommend for treatment of diarrhoea and in particular of diarrhoea in children. Analyses have shown that aploma has a high pectin content, and to this its astringent properties are ascribed. The preparation was produced at the instigation of the Children's Clinic of Munich University, and several of the staff of this clinic have published articles recording its beneficial therapeutic effects. It is marketed in England by Messrs. Coates and Cooper, Ltd., 94, Clerkenwell Road, E.C.1.

HEREDITY A MINOR FACTOR IN MENTAL DEFICIENCY

BY

CHARLES McNEIL, M.A., M.D., F.R.C.P.ED.

EDWARD CLARK PROFESSOR IN CHILD LIFE AND HEALTH, UNIVERSITY
OF EDINBURGH

The subject of mental deficiency has been brought to the notice of the medical profession and of the public by the recent report of the Departmental Committee on Sterilization.* Although the popular opinion of mental deficiency is that it is one disease and is inherited, it has long been recognized by medical men that a number of clinical types go to make up the aggregate of cases in the population. An important question raised by the report is the distribution of hereditary and non-hereditary cases in this aggregate. This question can only be answered by the investigation of a large number of cases; and these cases must be not only a large but a representative sample of the condition as it occurs in the general population. Such investigations have been made and are being made in institutions for mental defectives; but the criticism had been made of these institutional statistics that cases regarded as hereditary tend to be concentrated there, and that they do not form a good sample. A better sample would be one drawn from all classes of the population, and dealing with cases at an earlier age than those in institutions.

Dr. John Thomson's Analysis

The late Dr. John Thomson published in 1924 an analysis of 952 cases of mental deficiency¹; and all of these were under 5 years of age at their first examination. They were drawn from his private practice and from a special hospital clinic, which he established in 1904 for the clinical study of these cases; and they were based upon a total of about 1,200 cases, the remainder of which were over 5 years, and were excluded from his analysis. Here we seem to have a really good sample of mental deficiency as it occurs in the general population in early childhood—an investigation of a very large number of cases by one man, expert in this subject, and recognized as an accurate clinician, his study extending over twenty years and following up many of the cases for years. This investigation is the largest and best of its kind that has been carried out in this country. It is, and will probably long remain, the classical clinical study of mental deficiency. It seems to have been overlooked, and it is appropriate to call attention to it at the present time, and to make some comments.

Dr. Thomson divided his total into nineteen clinical groups, arranged in the two larger groups of primary and secondary amentia according to Tredgold's classification. In a paper which I published some years later² I arranged his clinical groups (without any alteration of the groups themselves) under the classification of ante-natal, natal, and post-natal, for reasons that will appear presently; and I also added forty-eight cases, taken consecutively from his hospital records between the publication of his paper and his death in 1926, in order to bring the total up to 1,000. This analysis of 1,000 cases is shown in Table I.

This classification of the cases shows that 65 per cent. were ante-natal in origin (and this figure should be a little higher, as some of the hydrocephalus group must have arisen in the ante-natal period), while 20 per cent. were natal, and due to trauma and vascular lesions of the brain at birth. Thus 85 per cent. of the cases were congenital, while 15 per cent were post-natal. It shows also the large number of known pathological conditions that cause mental deficiency.

TABLE I.—Mental Deficiency. 1,000 Cases under 5 years
(John Thomson)

Ante-natal	Natal	Post-natal
Simple primary amentia ... 292	Spastic diplegia, from birth injury 89	Hydrocephalus and meningocele ... 58
Mongolism ... 246	Spastic diplegia, with doubtful birth injury ... 28	Epilepsy ... 44
Microcephalus ... 25	Spastic diplegia, with no birth injury ... 34	Hemiplegia ... 16
Congenital syphilis 29	Birth injury, without spastic diplegia ... 47	Following cerebro-spinal meningitis 12
Sporadic cretinism 46		Encephalitis lethargica ... 4
Tuberous sclerosis 3		Hypopituitary ... 2
Various ... 4		Various ... 17
Amaurotic family idiocy ... 4		
Total ... 619	Total ... 198	Total ... 153

HEREDITARY AND NON-HEREDITARY CASES

Although Dr. Thomson himself made no attempt to divide the cases into those that are hereditary and non-hereditary, an attempt at such a grouping may be made. Taking the non-hereditary group first, the natal and post-natal cases can be put into it: and of the ante-natal group, the cretins and syphilis also belong to it. I propose to add also to it the large total of 246 mongols, for the following reasons. The cause of mongolism is unknown; it may be due to some fault in the developing embryo, or to some condition of the uterus, or even to some defect in the germ. Even if it were shown to be a genetic defect, it is accidental and not essential, and is not hereditary. The mongol leaves no heirs; and his parents, his brothers and sisters are not more liable to beget mongols than other people. This inclusion of mongols in the non-hereditary group is already done in American statistics.

Let us now deal with the hereditary group. The four cases of amaurotic family idiocy certainly belong to it: the hereditary mechanism is here beyond dispute, and is recessive Mendelian. There only remain the very large group of simple primary amentia, and a much smaller one, microcephalus. In these two groups heredity is believed to play an important part by most of those who have made a special study of the subject; but the hereditary factor is obscure, has not been convincingly demonstrated, and is still a matter of dispute. Meantime we may class these last two groups as uncertain; and so rearrange the total on a hereditary basis as follows:

TABLE II.—Mental Deficiency. 1,000 Cases under 5 years
(John Thomson)

Hereditary	Doubtful Hereditary	Non-hereditary
Amaurotic family idiocy ... 4	Simple primary amentia ... 292	Ante-natal, Cretinism 46
	Microcephalus ... 25	Ante-natal, Syphilis 29
	Various ... 4	Ante-natal, Mongolian ... 246
		Ante-natal, Tuberous sclerosis ... 3
		Natal (total) ... 198
		Post-natal (total) ... 153
Total ... 4	Total ... 321	Total ... 675

Thus in a large number of cases, a sample representative of all types of mental defect and of all classes of the population, heredity in the sense of transmissible defect or disease plays no part in a large majority of the cases (two-thirds); it is believed to play some part, obscure and uncertain, in one-third; and its action is definite and certain in only a negligible fraction of the whole.

Let us now examine the middle division of Table II, where the influence of heredity is obscure. It is made

* See *British Medical Journal*, January 27th, 1934, p. 161.

up to a great extent by the simple primary amentia group. This is not a homogeneous group of one clinical type, it is a residue of cases, which cannot be placed in any of the other groups, but which otherwise differ both in their bodily condition and in their mental behaviour. But it is a large group, the largest of all; numbering in this series nearly a third of the total; and in it the mental defect is ante-natal, so that it must be due, either to some morbid process after conception, or to genetic defect or weakness. As no morbid intrauterine process has been discovered, it is natural to suspect a hereditary taint in all or in a great majority of the cases in this group; and especially as among them we have the degenerate class, where one or both of the parents are defective both in mind and in body, and tend to beget defective children.

In this degenerate group the action of bad heredity is certain; yet it is not the transmission of a Mendelian defect, but that general blend of the constitution of the parents in the child which is the universal hybrid inheritance of man. Further, it must be remembered that the morbid factors of environment are also specially active in this group. It would be a serious mistake to ignore the importance of this group; they put a heavy social burden upon the community, and everyone would welcome measures to reduce their numbers. It is agreed, however, that in institutions the group of degenerate defectives form only a small minority, and that the great majority of the simple primary aments there have parents who are normal in mind. My own experience of simple primary amentia is based upon a large number of cases seen both in hospital and in private practice, which may be taken as a fair sample of this type of defect as it is found in the general population. In the overwhelming majority of cases the parents have been men and women of average or superior intelligence, character, and general health. If these cases are hereditary, what, then, is the nature of the hereditary mechanism? If they are due to the transmission of a recessive Mendelian defect, we ought to find the same types of amentia cropping up in successive generations of these families. Such a regular re-appearance of similar types has not been found in this country, although it is said that a type of recessive Mendelian feeble-mindedness exists in certain districts of Sweden. There remains the theory of a neuropathic constitution, which is not Mendelian inheritance of one fixed and recurrent defect, but an inherited liability to a group of morbid conditions, including mental defect, insanity, epilepsy, and nervous instability. It is not a satisfactory theory, and the evidence in support of it is not convincing; but in the absence of other evidence of ante-natal defect or disease it is widely held. But it is well to remember that congenital syphilis was regarded not so long ago as hereditary: it is now proved to be an ante-natal infection. Sporadic cretinism also was once hidden in the general mass of inherited mental defect, and is now a classical example of an ante-natal endocrine defect. It is reasonable to believe that further clinical investigation of this miscellaneous group of ante-natal mental defects, labelled simple primary amentia, will extricate from it other types of ante-natal disease and defect, and that these, when recognized, may be cured like syphilis and cretinism, or prevented. Heredity does play a part in the production of cases of simple primary amentia; whether that part is large or small we do not know. It is a reasonable assumption that morbid conditions of intrauterine environment are also playing a part. In our present state of ignorance the question of the respective parts played by hereditary and non-hereditary factors in the production of cases of simple primary amentia is unsettled and uncertain; and no dogmatic statements are warranted.

NEED FOR AN AUTHORITATIVE STATEMENT

For some years past active public propaganda has been carried on, by which our people have been led to believe that mental defect is nearly always inherited. They are told that at least 80 per cent. of all cases are accounted

for in this way. It is very desirable that some authoritative statement should be made in the medical press at the present time, showing how this percentage figure has been obtained, and giving some details of the actual investigations, with the numbers of cases and the methods employed.

Meantime, it is common ground with us all that the great majority of the parents of mentally defective children are men and women of average or more than average intelligence and character. I have had a fairly long and extensive experience of the mentally defective child and its mother at the Edinburgh Hospital Clinic, and I have been convinced of two things: the mother of the child is above rather than below the average in intelligence; and in her devotion to the child, and in the courage and cheerfulness with which she faces her heavy task, she shows the highest moral qualities. She might well be spared the additional pain and humiliation caused by all the popular lecturing and preaching on mental defectives. The appearance and behaviour of mentally defective persons, both children and adolescents, create, and naturally enough, a feeling of repugnance and disgust in the mind of the ordinary man; they seem to be less than human. But they are the same human clay as ourselves, only marred somehow in the making.

CONCLUSIONS FROM THIS STUDY

Finally, some general statements may be made, based upon this study of 1,000 cases of mental deficiency, constituting a large and representative sample of the condition as it occurs in the population, and carried out by a physician whose experience of the subject was very extensive, and whose reputation for clinical accuracy was very high.

The great majority of the cases were congenital (85 per cent.), and a large majority were ante-natal in origin (65 per cent.).

A large majority (two-thirds) were the result of non-hereditary morbid processes, acting before, during, and after birth.

In only a small fraction (0.4 per cent.) was mental defect known to be produced by the mechanism of Mendelian inheritance.

In a larger group (one-third of the aggregate), an important influence of heredity may be accepted for those cases where the children were born of defective parents. These cases, however, form only a small minority of this group. In the great majority, where the parents were of normal mind, the influence of heredity was uncertain and obscure.

The general conclusion appears to be that heredity plays a very small part in the production of congenital mental deficiency, and that its influence in this respect has been very greatly exaggerated.

- ¹ Thomson, John: *Edin. Med. Journ.*, May, 1924.
- ² McNeil, Charles: *Ibid.*, October, 1931.

We have received from the secretary of the Birmingham Hospitals Centre, Captain J. E. Stone, a copy of the first number of *The Samaritan*, a quarterly journal published by the Birmingham Hospitals Contributory Association. This includes messages of encouragement from the Lord Mayor (Alderman H. E. Goodby) and the Lady Mayoress, and the chairman of the Committee of Management, Colonel Bertram Ford. The Lord Mayor writes: "Birmingham is proud in the knowledge that the hospitals contributory organization, as formed in this city, has served as a model and incentive for the rest of the country." The Lady Mayoress refers to the splendidly equipped ambulance service, which, with the co-operation of the St. John Ambulance workers, has done such efficient work during the last few years. An article on the Birmingham General Hospital is contributed by Mr. A. H. Leaney, the house governor.

THE NORMAL LEUCOCYTE COUNT

There are clinicians who place too blind a reliance on laboratory reports, treating them sometimes as if they afforded the one haven in a stormy sea of diagnostic doubt. This confidence may be unmerited, either because "facts" in a report are not facts, a circumstance for which there may be more than one explanation, or because the facts are wrongly interpreted. The performance of a blood count is usually looked upon as a simple if tedious proceeding, and it is certainly not beset by such possibilities of error as are examinations in which the specimen itself may only be secured with a varying admixture of other material; but its finer accuracy depends very much on the experience of the operator, and on the side of interpretation we have A. F. Bernard Shaw's exposure¹ of the "haemoclastic crisis" fantasy to warn us that an accepted significance may be ill founded.

A still more severe blow at any attempts to base conclusions on minor variations in the leucocyte count has been delivered by Simpson,² who set out to determine the normal limits of the count in order to assess at their proper value the variations observed in the blood of x-ray and radium workers. He confirms the previous observations of Shaw, Sabin and her co-workers, and Doan and Zervas, that in the normal subject the numbers of leucocytes in the peripheral blood are subject to wide and rapid fluctuations: the extremes in a single individual were counts of 2,800 and 11,200 per c.mm., while even higher figures were sometimes obtained in other subjects apparently in perfect health. Whereas other workers have sought to identify rhythmic "tides" on which these variations depend, Simpson, beyond confirming a moderate average increase in the count as the day proceeds, could observe no sort of constancy in these fluctuations. A series of counts performed regularly on a single individual at the same time of day exhibited the usual variations, and successive counts at increasingly short intervals, even of five minutes, two minutes, and finally of one minute, betrayed nothing in the nature of a steady rise or fall, but only a capricious irregularity, which it is perhaps not altogether inappropriate to compare to the density of clouds of smoke rising from a fire. It is natural at this point to inquire whether the methods used were accurate: this appears to have been sufficiently tested and demonstrated. And what would be the results of simultaneous counts? These, although too few in number, were performed on blood from adjoining fingers, and gave concordant results. It is a little difficult to picture the conditions in the circulation as a whole which underlie these rapid fluctuations: it would be interesting to repeat these studies using venous

blood, in order to demonstrate with certainty that the changes observed affect the circulation as a whole, and are not dependent on local conditions.

Whatever the explanation of these results may be, the fact remains that leucocyte counts performed in the usual way vary over a very wide range, and results which in a patient would confidently be taken as evidence of a leucopenia or a moderate leucocytosis are obtainable in the healthy subject: whether the count is high, "normal," or low is a matter of the purest chance. Although the variations affect chiefly the polynuclear cells, lymphocytes are also subject to fluctuation, and in four out of thirty-one healthy subjects Simpson obtained lymphocyte counts below 1,500 per c.mm., the figure given by Mottram as the low limit of the normal, the transgression of which in an x-ray or radium worker indicates damage to the bone marrow. What is now to be done about blood examinations in those exposed to irradiation is by no means clear. The alternatives appear to be to continue the present practice of single counts at intervals of three or six months, ignoring minor changes and watching closely only for the onset of anaemia; or to perform a dozen counts in a single day in order to obtain a representative average. This laborious proceeding would only be worth while if we could interpret its results with certainty, but the whole literature of blood changes in those exposed to irradiation is so confused and contradictory, owing doubtless in part to the fallacies which we have here been considering, that no such interpretation yet appears possible. Meanwhile clinical medicine as a whole has received a warning against too close an interpretation of the findings in a blood count. A false assumption based on unreliable data is much worse than having no data at all: this may perhaps mean that some blood counts were better not performed at all, and a good deal of soul-destroying labour would be saved if they were not. Some would go so far as to say that an accurate haemoglobin estimation will ordinarily yield all the information that is needed in states other than actual blood diseases. This, of course, implies that the function of the clinical pathologist is to confirm and define conditions of which there is clinical evidence, and not to conduct innumerable fruitless investigations for the sake of an occasional unlikely or unexpected discovery.

SIR ROBERT JONES

Mr. Frederick Watson has made a notable contribution to the history of medicine in *The Life of Sir Robert Jones*.¹ This volume is at once a tribute of filial piety from a son-in-law and at the same time a serious study of the development by H. O. Thomas and his nephew, Robert Jones, of orthopaedic practice in the last fifty years. Mr. Watson appears to take the view that fifty years ago, outside the practice of H. O. Thomas in Liverpool, orthopaedic surgery was not practised or

¹ *British Medical Journal*, 1925, i, 914.

² *Brit. Journ. Radiol.*, 1933, vi, 705.

¹ *The Life of Sir Robert Jones* By Frederick Watson. London: Hodder and Stoughton. 1934. (Pp. 327; 10 illustrations. 12s. 6d. net.)

taught in the United Kingdom. We think that this is an error. There were in London three orthopaedic hospitals where the conservative treatment of tuberculous joints and of deformities generally was successfully carried out, at a time when surgeons of the general hospitals were freely excising joints, often with disastrous results. It is true that, owing to an ingrained dislike of specialism, orthopaedic surgery was not highly esteemed by the leaders of the profession or by the medical press of those days, and its scope was narrow. Progress began in the United States, where conditions were more favourable and where the American Orthopaedic Association was founded with thirty-five active members in 1887. Before that event progressive American surgeons visiting Europe had discovered the remarkable clinic of H. O. Thomas in Liverpool, and had made known his teaching on their return to America. The British Orthopaedic Society was started by surgeons who attended the Annual Meeting of the British Medical Association at Bristol in 1894, of whom Robert Jones was one. It had thirty or forty members, and flourished at first. It published three volumes of transactions for the years 1894 to 1898, in the third volume of which is a report of a demonstration by Jones of Calot's method of correcting angular deformity of the spine, a method at one time enthusiastically acclaimed by some surgeons, but now long since given up. Despite its promising beginning the society faded away, presumably for personal reasons. It is noteworthy that, to avoid jealousies, it had no president, its only officers being a treasurer and secretaries. A chairman was elected *ad hoc* at each meeting.

Robert Jones was born in 1857 at Rhyl in North Wales, but soon after his birth his father removed to London, where he engaged in journalism, and where Robert's boyhood was spent. Not long before his father's early death he went to live with his aunt and her husband, H. O. Thomas, and became a student at the Liverpool School of Medicine in 1873. After obtaining the diploma of M.R.C.S. England in 1878 he became assistant to his uncle by marriage, of whose practice he had already had some experience. In 1889 Jones was elected surgeon to the Royal Southern Hospital, Liverpool. When the great work of making the Manchester Ship Canal was undertaken the contractors realized that special provision must be made for the medical and surgical needs of some 20,000 navvies and other workmen and their dependants. The young surgeon to the Southern Hospital was chosen to be medical superintendent of the works, with the duty of appointment of matrons of the hospitals and the selection of fourteen surgeons who were to serve under him. This appointment was no sinecure. It involved the supervision of three temporary hospitals as well as the performance of many operations. The power of organization which this work revealed, and the qualities of decision in emergency and rapid action which it required, were still further to be tested and triumphantly demonstrated in the Great War. H. O.

Thomas died in 1891, and Robert Jones succeeded to his large and comprehensive practice. Thomas was a general practitioner with a strong surgical and mechanical bent, who became from force of circumstances an orthopaedic surgeon. Jones was a general surgeon who practised orthopaedics, and he only gradually gave up general surgery, and, like his uncle, became by force of circumstances a specialist. Jones owed much to Thomas, but the latter, had he lived, could never have approached the achievements of Jones, owing to his pugnacity and lack of the power of suffering fools gladly.

We believe that the memory of three outstanding achievements will be linked with the name of Sir Robert Jones when time's perspective has adjusted itself. The first, in order of occurrence, is the introduction of the Thomas splints for recent gun-shot fractures; secondly, the curative workshops; and, thirdly, the National Scheme for the Care and Cure of Cripples, to which, with the aid of Mr. Girdlestone, he devoted so much time and thought. Probably the last-mentioned will prove to have made the deepest impression. The history of all these and other activities, such as his writings, will be found in Mr. Watson's *Life*. Unflagging energy, tireless industry, unruffled temper, and a winning charm of manner—these were characteristics which were ancillary to his great skill and ability. In 1907 Dr. William Mayo of Rochester, Minnesota, no mean judge, wrote: "I must place Mr. Robert Jones as one of the greatest surgeons it has been my good fortune to meet."

THE MALARIA CAMPAIGN

It is only a few weeks since we noted how regular and rapid is the system of mutual communication about infectious disease incidence which has grown up in the past ten years between the Health Departments of the Governments of the world. The Health Section of the League of Nations has now issued a survey of the work done during that period in the international field for the prevention and treatment of malaria. At the end of 1918 there was a general recrudescence of malaria. A serious situation had arisen owing to war conditions, which led to an almost complete suspension of anti-malarial measures in many countries, a general disorganization of health services, a lack of doctors for civilian work, an insufficiency of quinine, and inadequate funds. One of the most important factors seems to have been the movement of populations. Persons more or less resistant to local strains were found to be not immune to foreign strains, while immigrants had no resistance against the local virus. Bad housing conditions, famine, and many other circumstances called for study with a view to preventive measures and a reconsideration of the whole question of treatment. The reappearance of malaria in districts from which it had vanished threw doubt on the value of methods hitherto employed in combating the disease. It soon became clear that international measures were called for, the

problem being too large and too complicated for individual Governments with the means at their disposal. Accordingly in 1923 the Health Committee of the League appointed a subcommittee of experts, in order to obtain precise knowledge about the distribution and character of the disease. The original subcommittee later became the Malaria Commission, which now consists of fifty-four members. Attention was directed to three specific problems: anophelism without malaria, production and sale of quinine, organization of epidemiological inquiries in heavily infected countries. The Commission, besides arranging study tours and collective inquiries, has sent individual experts to certain countries to report on the situation. Meanwhile a general inquiry was set on foot to ascertain the prevalence of malaria throughout the world. Ninety-three health administrations of malarial countries, representing three-quarters of the population of the globe, furnished information. It was found that the cases treated during the last year covered by the inquiry numbered 17,750,760.

In 1927 the Commission, as a result of this work in many lands, laid down a number of principles which ought to govern antimalarial work in Europe. It was agreed that the first step must be to treat the sick, and the second to kill the malaria parasite, either by treatment in the patient or by destroying the infected mosquito. General inquiries made under the auspices of the Commission clearly showed, however, that the methods adopted must vary widely according to locality and the general circumstances of the infected population. Without careful study of local conditions a method yielding good results in one malarial country cannot be depended on in another. These conclusions showed the need for allowing young malariologists to gain experience by work in different countries. Hence, from 1926 onwards international courses have been held in France, Germany, Great Britain, Italy, Spain, and Yugoslavia, and many doctors attending them have been granted scholarships by the Health Organization of the League. The malaria courses in Europe do not, however, meet the needs of medical officers intending to work in non-European countries where the conditions are dissimilar; for them a course is being arranged at Singapore, beginning on April 30th, to be followed by field work in Indo-China, the East Indies, Malaya, or elsewhere. A conference of experts held in Geneva five years ago decided that several questions were important enough to need international co-ordinated research. The inquiries to be made were grouped under three main heads: (1) treatment of malaria and its importance in malaria prevention; (2) housing and malaria; (3) anophelism without malaria and malaria in deltas. Of these, the inquiry into treatment was entrusted to the secretariat of the League, who published the results in 1932. The quantity of quinine or of alkaloid mixtures necessary to meet the needs of the eighty-eight malarious countries of the world is put at 1,387 metric tons a year, the present consumption of quinine falls short

of 600 tons. The greatest obstacle to a larger consumption appears to be the cost of treatment, and the Commission has recommended a standard formula for a total alkaloid mixture (totaquina), researches into the efficacy of which have been carried out in various countries. The efficacy of other drugs has also been investigated, and the Commission published the results in June last. Put very briefly, three conclusions emerge. Quinine is still the best remedy for preventing the onset of clinical symptoms after infection; quinine and atabrin are the best remedies against the attack; but no drug can guarantee patients against relapse.

This ten years' study of antimalarial measures makes it even plainer than before that the many problems must be tackled on a world-wide scale. Most of the factors in the epidemiology of malaria present both general aspects and aspects which are peculiar to different localities, climates, races, degrees of immunity of the population, social and economic conditions, the virulence of the parasitic strain, and other features that vary from district to district. It is this mix-up of general and specific factors that makes organized international research so necessary. The Malaria Commission, representing all schools of malariology, acts as a clearing-house for information and experience from everywhere.

GLAUCOMA SIMPLEX

It is well known that the early diagnosis of glaucoma simplex is often a matter of the greatest difficulty. As may be expected, therefore, no royal road to the detection of the first stages of the disease is to be found in a group of recent papers. Methodical vigilance, and painstaking attention to detail in every case examined, alone will permit of treatment being started when it can do most good. The analytical figures, given by S. B. Marlow,¹ relative to the first symptoms discoverable, are inconclusive, but it is noteworthy that premature presbyopia has no relation to glaucoma simplex. The statement that there is no relation between the extent of field defects and the duration of the disease seems somewhat dogmatic, since, in such an elusive disease, the point at which the trouble is first recognized depends upon so many human factors. Photography of the optic disk at frequent intervals is suggested as a method of watching the progress. Even if one could honestly persuade patients that no harm would come of many exposures of the retina to intense lights, it is doubtful if many would submit to such a procedure. The author points out, with justification, that, though the tonometer, properly used, can be of the very greatest assistance, cases of glaucoma occur in which no increase of tension can be demonstrated. He makes the very practical suggestion that the light minimum can be easily determined without complicated apparatus by reducing the illumination in the perimeter to a degree arbitrarily chosen by the examiner as a useful standard. A. B. Reese,² in describing the pathology of glaucoma, expresses the present imperfect knowledge of the causation of the disease when he says that "peripheral synechiae cause

¹ *New York State Journ. Med.*, 1933, xxxiii, 1423.

² *Ibid.*

glaucoma, and glaucoma causes peripheral synechiae." No mention is made of the fact that there can be remissions of the glaucoma with persistence of peripheral synechiae. He gives a very instructive explanation of the causation of proliferative and non-proliferative atrophy of the iris. The theory, quoted from Schnabel, according to which cupping is considered to be due to the collapse of cavernous atrophic spaces in the nerve head, though a very attractive explanation of the cupping found in cases with no detectable increase in intraocular tension, is, however, not generally accepted. The operative treatment will for some time to come be a personal matter with each individual surgeon. "Whatever method the operator can use with confidence is the best method for him" puts the matter in a nutshell. A. Knapp³ employs the Lagrange operation in selected cases, but does not exercise the same discrimination with the trephine. It is therefore difficult to compare his results in these two operations. After so many glowing accounts of cyclodialysis from other authorities, it is useful to note that "the results have been very disappointing, principally because one never knows how long the good result may last, and another serious objection is that the return of tension may be abrupt and stormy." He also looks with disfavour on iridotaxis. W. Zentmayer,⁴ in discussing the medical treatment, accepts the importance of surgical intervention. In contradistinction to the general practice in this country, he begins treatment with the weaker miotics in dilute solutions. Though massage is of assistance in certain cases, few patients will carry it out properly and conscientiously. As is usual in America, great stress is laid on dietary and a very complete investigation of the endocrine, vascular, and nervous systems.

COST OF LONDON HEALTH SERVICES

At its last meeting before Easter the London County Council considered its estimates for the year 1934-5. The vote for maintenance expenditure for the general hospitals was put down at £469,000; for the infectious diseases hospitals at £156,000, and for sanatoria and children's hospitals at £86,000. The vote for the district medical service was £6,500, for pathological laboratories £8,000, and for maternity and child welfare and the administration of the Midwives Acts £6,300 (the Council is not the maternity and child welfare authority for London, these duties being discharged by the borough councils). The vote for the diagnosis and treatment of venereal diseases was put down at £57,000. The scheme is one in which six neighbouring county councils and three urban corporations participate with the L.C.C. The Hospitals and Medical Services Committee states that the agreements with the voluntary hospitals for this purpose have now been in operation for seventeen years, and the time has come when they should be reviewed in the light of experience. The voluntary hospitals concerned will, when notified of the grants for 1934-5, be informed that it is proposed to review the arrangements during the year. The various hospitals at which venereal diseases clinics are conducted make provision for in-patient treatment. The number of in-patient days in 1933 in respect of patients from all areas was 52,581, comparing with 54,023 in 1932, and 56,541 in 1931.

The number of new cases of venereal diseases was 15,802; other cases to the number of 11,236 attended and were found to be non-venereal. The new cases of syphilis numbered 4,710, of gonorrhoea 12,104, and of soft chancre 195. Nearly 40,000 pathological examinations were made for practitioners, and the names of 520 practitioners in the county were on the approved list for the supply free of cost of salvarsan or its substitutes. Facilities for instruction at the clinics in modern methods of diagnosis and treatment have so far been limited to medical practitioners and medical students. It is now desired to extend the facilities to pupil midwives, and certain clinics have been asked to make arrangements for this purpose. The response has been encouraging; and agreements with the hospitals for 1934-5 will include a clause to the effect that the hospital shall, if required, provide for the instruction of pupil midwives in venereal diseases.

Actions have been commenced in the High Court against the L.C.C. and the medical superintendent of one of its hospitals for damages on behalf of certain infant patients who contracted an infectious disease while under treatment in the hospital. The Council has power to indemnify its officers in respect of damages and costs in proceedings brought against them for acts done in the execution of their duty, but the Court might overrule the indemnity on the ground that the case is such that public funds should not be utilized for the purpose. The circumstances of this particular case, in the opinion of the Hospitals and Medical Services Committee, justify the exercise of the discretion vested in the Council, and it is considered, moreover, highly desirable from the point of view of public policy that the defence of the two actions should be in the same hands. The committee proposes, therefore, that the Council should offer, if the medical superintendent so desires, to undertake his defence as well as its own, and that the Council, in the special circumstances of the case, should indemnify the superintendent in respect of any costs or damages that may be awarded against him.

ACTION OF WATER ON LEAD

Drinking-waters attack lead pipes and, taking up traces of the metal, give rise to lead poisoning in consumers. This statement is broadly true. Plumbosolvency and plumbism occur. It is common, if vague, knowledge. But when instead of vague generalities a slightly closer view is attempted, and answers are sought to such seemingly elementary questions as "Why plumbosolvency?" and "What is plumbism?" it soon appears that there is a lack of precise information on many points, as well as much divergency of opinion among recognized experts. As a step towards a clearer understanding of the various questions involved—which as a group are of much importance to the health of the community—the Water Pollution Research Board has arranged for a laboratory investigation to be carried out into the conditions affecting the action of water on lead. In the first place, it instructed a survey to be made of what has been written on the subject, and a summary of the data collected appears in a report just issued.¹ In this work attention is mainly directed

³ *Arch. Ophthalmol.*, 1933, x, 298.

⁴ *New York State Journ. Med.*, 1933, xxxiii, 1423.

¹ *The Action of Water on Lead, with Special Reference to the Supply of Drinking Water: Summary of Existing Knowledge.* By H. Ineson, M.A., D.Phil. Water Pollution Research. Technical Paper No. 4. London: H.M. Stationery Office, 1934. (2s. net.)

to: (1) the maximum permissible lead in drinking-water; (2) the factors causing action of water on lead; and (3) the methods of preventing such action. The observed values of lead in water samples examined are shown to vary within wide limits. As regards a permissible maximum, some authors consider that any trace of lead found should promptly veto the further use of lead pipes with the supply concerned. Others are prepared to view with equanimity up to 0.1 part of lead per million. Most, however, would apparently consider 1 part per million as gross contamination. Between 0.1 and 1 it is at present debatable land. As regards the factors inducing plumbosolvency discrepancies of the same kind emerge. One authority states that sulphuric acid promotes the action on lead; another, that it protects the pipes. Again, one says that carbon dioxide is the primary active agent; another, that it exerts a restraining influence. Similarly with the methods of preventing plumbosolvency there is great variation in both opinion and practice, and in this connexion accounts are given of the protective measures adopted by the Yorkshire and Lancashire towns and Continental and other centres. The report, however, is much more than a succession of conflicting antitheses as the random samples cited above might possibly suggest. It exhibits in summary form a comprehensive mass of important information. Though strongly condensed, it is amply equipped with references to original papers. It is a work which, for their guidance, should be in the hands of medical officers, water engineers, and members of councils or public boards who may have it in mind at this time to embark upon any undertakings for the protection of water supplies containing lead or potentially plumbosolvent.

HOSPITAL DEVELOPMENT IN LONDON.

On page 126 of the *Supplement* to this week's issue appears an account of the meeting arranged by the Metropolitan Counties Branch of the British Medical Association for a discussion by members of the teaching staff of London's hospitals of the problems of London's hospital development. It was evident from what was said that London consultants are not altogether easy about the state of things as they are, and as they may come to be. The development of the municipal hospital service as a result of the Local Government Act of 1929 has had its repercussions on the voluntary hospital system. In London the financial resources of the London County Council give it scope and power to reorganize and equip its hospitals in such a way as to challenge in efficiency, if not yet in personnel, the teaching hospitals which depend economically upon voluntary assistance. This is all to the good for the community which these two systems serve, but if the voluntary hospitals are to continue in the proud position they have maintained up to the present there will be need for a more planned and concerted effort and a greater awareness of their economic and medico-political problems. The proposal to be put to the Hospitals Committee of the Metropolitan Counties Branch that one-half of its members shall be representatives of the twelve London teaching hospitals is a move in the right direction. If this proposal is accepted these representatives would constitute a nucleus of opinion that

ought to be of great value in the development of hospital services, not only in London, but in the country at large. "Whither medicine?" is a question that pre-eminently concerns the younger members of the profession, and we may express the hope that the junior members of the teaching staffs will not be forgotten when it is decided whom to elect on the Hospitals Committee.

PATHOLOGICAL MUSEUM, BOURNEMOUTH

We are asked to make further reference to the Pathological Museum which is being arranged for the Annual Meeting of the British Medical Association at Bournemouth next July. This will be held in the same building as that in which the Sectional work is carried on, and the material will be grouped under: (a) exhibits bearing on discussions and papers in the Sections; (b) specimens and illustrations bearing upon recent research work; (c) instruments relating to clinical diagnosis and pathological investigation; (d) individual specimens of special interest, or a series illustrating some particular subject. It is also hoped to have exhibits relating to neurology and to heredity and mental and physical deterioration, and a series of x-ray and other photographs. The committee is anxious for the co-operation of pathologists and others in securing specimens of medical interest on the lines indicated above. Offers of assistance should be sent to the honorary secretary of the Museum Committee, Dr. C. G. H. Morse, 10, Madeira Road, Bournemouth.

SIR ROBERT McCARRISON

The governing body of the Arnold Flinker and Julius Wagner-Jauregg Foundation of Vienna for research on goitre and cretinism has awarded the Foundation's prize of 2,000 Austrian shillings to Major-General Sir Robert McCarrison, I.M.S., for his researches into the aetiology of goitre, upon which he presented a report at the second International Congress on Goitre, held in Bern last summer. As this prize had never before been awarded to a foreigner the statutes had to be altered for the purpose of recognizing Sir Robert McCarrison's work.

Major Charles H. H. Harold, M.D., R.A.M.C., at present assistant director of hygiene, Southern Command, has been appointed Director of Water Examinations by the Metropolitan Water Board, in succession to the late Sir Alexander Houston.

We much regret to announce the death, on March 25th, after an operation, of Mr. David Lees, consulting surgeon for venereal diseases to the Royal Maternity Hospital, Edinburgh, and medical officer to the venereal clinic of the Royal Infirmary.

Colonel Arthur Lynch, M.R.C.S., whose versatility of mind and varied career have been made familiar to all newspaper readers, died in St. Mary's Hospital on March 25th, at the age of 72.

At an extraordinary general meeting held on March 23rd the Governors elected Viscount Leverhulme president of Epsom College in succession to the late Lord Burnham.

TRAINING THE HOSPITAL ALMONER

SIR FARQUHAR BUZZARD ON WHAT AN OLD PROFESSION CAN TEACH A NEW

In an address to the Institute of Hospital Almoners, of which he has lately become president, Sir Farquhar Buzzard, Bt., dealt with some aspects of professional training in general, and gave to the members of this comparatively new profession some counsel which has an interest for a wider circle than those to whom his remarks were immediately directed. As a result of his long experience on the staffs of four London hospitals, he paid tribute to the manner in which the almoner had gradually bridged the gulf between the treatment prescribed by the hospital doctor and its practical application. These four hospitals, by the way, included the Royal Free, the first institution to establish an almoner—Miss Stewart; and St. Thomas's, where Miss Cummins, whom he described as "the Florence Nightingale, if not the Mussolini, of the movement," had served.

ASPECTS OF THE ALMONER'S WORK

He went on to refer to the results of a questionnaire sent out by the council of the Institute to hospitals all over the country, which showed that out of a sum of £9,185 spent on surgical appliances, 47.2 per cent. had been raised from the patients, 8.9 per cent. from hospital and almoners' funds, and the remainder from other agencies. Thus a large number of appliances (9,334) were provided at an extremely low cost to hospital funds, and the co-ordinating influence of the almoner helped the other agencies to carry out their functions in the best way. Of £12,734 spent on convalescent treatment for 5,509 cases, the patients provided 28 per cent. of the cost, the hospitals 18.6 per cent., and other agencies the remainder. Here again the almoner was able to arrange that only a small part of the cost fell on the hospital. The questionnaire had also yielded much interesting information with regard to the following up of patients after discharge from hospital. These patients fell into four categories: those in need of convalescence, appliances, or extra nourishment and help at home for a limited period; those requiring prolonged supervision or assistance in procuring diet and drugs to enable them to lead a more or less normal existence; the incurables, who required certain accessories and comforts; and, finally, cases the further history of which was specially desired for the purpose of research or statistics. Sir Farquhar Buzzard believed that the preventive aspect of the almoner's work would one day assume a more important role. It was through the medium of the almoner as interpreter and expositor that a knowledge of the advances made in practical medicine would reach the poorer classes of the population.

PREPARATION FOR A PROFESSION

Turning to the almoner's training, the speaker thought that something was to be learned from the history of the medical profession. The older profession had been taught by experience some lessons which were worthy of attention by a younger profession still experimenting and feeling its way. One advantage which the profession of almoner enjoyed over the medical profession was that its ranks were recruited by a process of selection and probation, and up to the present only candidates had been accepted who had completed a general education, so that the snare of early specialization had been avoided. It could not be too strongly urged that even after school life was over a girl needed a period of at least a year in which to widen her horizon before entering upon special preparation for the almoner's certificate. In order to become an efficient social servant some knowledge of all social strata was essential, and without it a woman's sense of perspective might be seriously and permanently warped. The interval between leaving school and entering upon professional training might be usefully employed in travel, university graduation, or the study of any subject having no immediate connexion with social service. All professions would benefit if some

such rule were in force, but the small profession of hospital almoners was almost the only one at present able to make it a universal requirement.

The medical student, less than a century ago, began his preparation by becoming an apprentice for a year or two to a doctor, afterwards joining a medical school and turning to the more academic side of his training. But with the advance of medical knowledge, the extraordinary development of the sciences ancillary to medicine, and the necessity for acquiring some knowledge of chemistry, physics, biology, anatomy, and physiology, the student's course was completely changed, and now he no longer came into contact with sick persons until that background of learning had been attained. A few regretted the old system, but nothing was less likely than its resuscitation. On the other hand, the pendulum of reform had perhaps swung too far in the opposite direction. The student might well see more of sick persons at an earlier stage of his curriculum, if only to enable him to compare health with ill-health and to appreciate better the significance of his studies. It could also be urged with justice that too much of the student's time was spent in scientific fields remote from those in which he would have to earn his living. The general desire was now being felt for a simplification of the curriculum in some directions, and a greater and more fluent continuity.

DANGERS OF AN OVERBURDENED CURRICULUM

Sir Farquhar Buzzard referred to one more criticism of the present medical curriculum, which was pertinent when considering that of another profession. During the last half-century, owing to a continuous series of new discoveries, large additions had been made to medical knowledge, and the student's burden had become heavier than he could bear. He had time perhaps to memorize, but certainly not to digest, the material put before him. If the profession he was now addressing were tempted to add to the training little by little there would come a time when that profession also would have to face an overburdened curriculum, and would be under compulsion to do something about it. He urged that the subjects which were essential for every candidate should be kept clearly in mind, together with the subjects which were merely desirable, or were necessary only to a few. The curriculum should embrace the essentials, and post-graduate study deal with the remainder. Moreover, not every moment of the curriculum should be filled even with essentials: time must be allowed for thought, for mental digestion, and for recreation.

An essential theoretical and academic background should be painted, and before it had time to dry the practical details of the foreground should be gradually filled in. In medical training the background had become so separated from the foreground that they might almost be thought to be separate pictures. The hard lines of demarcation, emphasized by too numerous examinations, had been allowed to split the picture into artificial compartments. The present task was to wash them out, and the process of restoration was none too easy.

WHAT SHOULD THE ALMONER KNOW OF MEDICINE?

Some had asked what an almoner ought to know of anatomy and physiology, medicine and surgery. Sir Farquhar Buzzard confessed himself doubtful as to the value of the time spent even by nurses in acquiring a smattering of anatomy and physiology, so it was not surprising if he deprecated the idea of almoners wasting much of their energies on a similar quest. Of course, it was to be hoped that in a day not far distant all girls and boys would be taught at school the elements of biology in such a way as to make them familiar with the general structure and functions of the human body. In the meantime, he doubted the wisdom of doing more than encourage students for the almoner's profession to gather what they could from suitable books. Still stronger was the argument against any attempt to teach them even the elements of medicine and surgery. What they would need in carrying out medical social service

was the ability to understand and interpret the strange language used by doctors, and, more important still, an intimate and sympathetic conception of the principles, ideals, and ethics underlying the practice of medicine. For those who wished to specialize in the work of mental hospitals, medical psychology must be regarded as a post-graduate study of importance, requiring perhaps special courses of instruction, and opportunities of gaining experience. The student who had taken a course of social psychology and philosophy was well prepared to assimilate the main features of medical psychology.

In conclusion, he said that the almoner's profession would be faced, as the medical profession had been, with the problem of specialization. Social services in the field of mental hygiene and in that of industrial psychology needed special qualifications, but these should be a superstructure based on an all-round knowledge and experience of social service as a whole. The best specialists in any walk of life were those whose grasp of subjects outside their specialties had reached and maintained a high standard. It was encouraging to learn that the demand for almoners was steadily increasing. It was a career undoubtedly only suitable for women who were well educated, physically and mentally sound, and had a genuine "urge" for social service.

Reports of Societies

BRONCHOSCOPY AND OESOPHAGOSCOPY

At a meeting of the Aberdeen Medico-Chirurgical Society held on March 1st, with Mr. ALEX. MITCHELL, president, in the chair, Dr. H. ROSS SOUPER read a paper on "Bronchoscopy and Oesophagoscopy in Diagnosis and Treatment."

After a brief outline of the development of peroral endoscopy within the past thirty years, and a description of the types of instruments in common use, Dr. Souper detailed the indications for bronchoscopy, more particularly in diagnosis. He pointed out that, while the part played by bronchoscopy in the search for, and removal of, foreign bodies had been realized for years, it was not by any means so widely recognized that bronchoscopy was a diagnostic method of the greatest importance in diseases of the lung, and quoted the dictum of Chevalier Jackson, that "in a general way it should be stated that diagnostic bronchoscopy is indicated whenever there is an unsettled diagnostic question." He referred to the uses of bronchoscopy in bronchiectasis, lung abscess, atelectasis, bronchial obstruction, asthma, tumours of lung, and post-operative complications. He then analysed his own figures of 188 bronchoscopic and oesophageal examinations, a total which excluded all bronchoscopies performed merely for the local injection of lipiodol and all direct laryngoscopies, with one exception, a somewhat unusual case of foreign body. The total of 188 was composed of 166 oesophagoscopies and 22 bronchoscopies, the latter figure being in Dr. Souper's opinion lamentably small. The two most numerous groups in the bronchoscopy cases were examinations for foreign body in the bronchial tree and for lung abscess. The importance of early diagnosis of foreign body was emphasized, and cases were described where, owing to the lack of appreciation of the presence of foreign body, it had been overlooked for months or even years. Four cases of tumour of the lung had been encountered, and two were described in detail. In both cases the diagnosis, while suspected on clinical grounds, had been absolutely confirmed by bronchoscopy.

INVESTIGATION OF OESOPHAGEAL SYMPTOMS

In the investigation of cases presenting oesophageal symptoms, the lecturer considered oesophagoscopy an essential method of examination. He pointed out that it had the advantage over x-ray examination in that it permitted direct inspection of the diseased viscus, and that the appearances obtained by x-ray examination of the barium-filled oesophagus might occasionally be misleading. He condemned whole-heartedly old-fashioned methods of investigating cases of oesophageal disorder by the blind

passage of the bougie and by attempting to remove a foreign body by probangs and other obsolete instruments. The cases of oesophagoscopies, numbering 166, were made up as follows: (a) foreign body, (b) cardiospasm, (c) cricopharyngeal spasm, (d) dysphagia and anaemia, (e) simple stricture, (f) peptic ulceration, (g) oesophagitis, (h) diverticula, (i) abscess, (k) functional dysphagia, (l) negative, (m) malignant disease. These groups were then discussed in some detail and some unusual foreign body cases described, more particularly two cases in which examination had been performed by bougie or other instrument before the patient was admitted to hospital, with an eventual fatal result in both. In one case an ulceration of the oesophageal wall was found three inches down the oesophagus proper, through which it was assumed the foreign body had passed. The patient in a few days died of uncontrollable haematemesis, and at necropsy a perforation of the oesophageal wall was found entering a small abscess on the left side, which had ulcerated into the left subclavian artery.

In the cardiospasm group there were twelve females and seven males, the youngest being 17 and the oldest 65. All had been submitted to oesophagoscopy with a view to confirming the diagnosis, and nearly all cases had been treated with success by the use of the mercury bougie. Only three patients in whom the oesophagus was so dilated that the bougie could not hit off the cardiac opening had been submitted to Walton's operation, one of whom had died of streptococcal gastritis. The lecturer delivered a warning against the too ready acceptance of a radiographic diagnosis of cardiospasm in an elderly patient, and showed slides of two cases where appearances suggesting cardiospasm were present which in reality masked malignant disease of the cardiac end of the stomach.

Seventeen cases, all female, of dysphagia and anaemia, or the Plummer-Vinson syndrome, had been investigated, and in seven cricopharyngeal spasm, and in six a cricopharyngeal web, had been found. These cases also improved by the passage of the mercury bougie and the administration of iron in suitably large doses. In the group of active ulceration two cases were those of ulceration following pregnancy, which, on subsequent examination, were found to have healed without stricture formation. Two slides of diverticula were shown, one at the upper end and one in the thoracic oesophagus.

MALIGNANT DISEASE OF OESOPHAGUS

The group of malignant disease of the oesophagus, fifty in number, was discussed in some detail. The importance of early diagnosis was stressed, and Dr. Souper urged that practitioners finding a patient of cancer age suffering from dysphagia, however slight, should send the case for early complete examination, as the only hope of satisfactory treatment was afforded by early diagnosis. He again repeated the warning against the indiscriminate use of bougies in patients presenting symptoms of oesophageal obstruction. In the fifty cases described twelve were situated at the introitus of the oesophagus, thirty-three in the thoracic oesophagus, and five at the lower end, with or without involvement of the cardiac end of the stomach. The youngest patient was 28 and the oldest 77, twenty-eight being males and twenty-two females. The difficulties of treatment were described and the different methods which had been tried were discussed. Dr. Souper believed that the most hopeful results had been obtained by the direct implantation of radon seeds into the tumour area of the oesophagus. Intubation by a radium-bearing tube had on the whole been disappointing, and Souttar's method of intubation had been used in two cases only, in both without the slightest benefit. The patients in whom radium and/or radon had been used numbered thirteen, all of whom had since died, but as every other case of proved malignant disease of the oesophagus was also dead, the radium was not to be blamed for the result. In one case radon seeds had resulted in complete disappearance of the tumour for a period of eight months, when recurrence took place. Early performance of gastrostomy was of the utmost help in the treatment of these cases, as it maintained the

patient's general condition, rested the oesophagus, and prevented irritation of the tumour. As his impressions of this group of malignant disease of the oesophagus, Dr. Souper summed up as follows:

1. Far too many cases are labelled neurotic or functional and are not investigated properly until the tumour has reached a size which renders any method of treatment almost impossible.

2. Every case of dysphagia occurring in a patient of an age where cancer is likely to develop, whether the symptoms are referred to any particular area of the oesophagus or not, should be without delay referred for the fullest investigation, an investigation which must include oesophagoscopy.

3. If, in any such patient, x-ray examination is negative, this should be accepted with reserve, as x-ray examination may fail to show an early oesophageal lesion. In two cases of this kind, where oesophagoscopy was suggested but declined, both died months later of obvious malignant disease of the oesophagus. Further, x-ray appearances suggestive of cardiospasm in a patient over middle age, whose symptoms are of recent development, should not lead one to the belief that the case is one of pure cardiospasm. It should certainly be submitted to oesophagoscopy to rule out the possibility of malignant disease.

4. No case of this kind should be investigated by the bougie.

OBSTETRICS AND GYNAECOLOGY

At a meeting of the North of England Obstetrical and Gynaecological Society, held at Sheffield on February 23rd, with the president, Professor DANIEL DOUGAL, in the chair, Mr. OLDFIELD (Leeds) showed a specimen of malignant teratoma of the testis in a girl aged 14.

D. S. was admitted to Dewsbury Infirmary complaining of pain in the right side of the abdomen for three weeks, with recent vomiting. On examination the patient looked like a normal girl of 14. There was an ill-defined mass in the lower abdomen, and on rectal examination a fixed tumour was found in the pelvis. Laparotomy was done: the tumour, attached by a broad base to the top of the left broad ligament, was found to be adherent to small intestine and omentum. The uterus and right tube were small, the right ovary absent. At the usual site of attachment of the right ovary was a porcelain-white structure, flush with the posterior layer of the broad ligament, as big as the impression of one's little finger: tiny cysts projected from it. In the position of the ovarian fimbria was another structure, the size of a coffee bean, and egg-shaped: it was whitish and solid. The tumour and the left tube were removed, the uterus and other structures being left. When a pathological report had been received from Dr. Carmichael, stating the tumour was a teratoma with epithelial malignancy, the abdomen was reopened and the uterus removed with most of the right broad ligament. Recovery was normal. Subsequently, a course of deep x-ray treatment was given. When the child was seen on February 7th she had returned to school. There was no sign of recurrence. The breasts were flat: the Aschheim-Zondek test was negative.

Histologically, Dr. Carmichael found the structure in the position of the right ovary to be an atrophic testis. The coffee-bean structure was a typical epididymis. The tumour itself was a typical tridermal teratoma of small cystic type: most of the tissue was fairly differentiated, but much was still embryonic, and large portions of a solid area were carcinomatous. It was assumed to be of testicular origin, partly because teratomata of this type were fairly common in the testis and very rare in the ovary, and partly because it was more reasonable to assume that the patient was a pseudo-hermaphrodite rather than a case of the much rarer true hermaphroditism. The patient's feminine habitus did not affect this view, because in cases of pseudo-hermaphroditism with bilateral testes the secondary sexual characters virtually always conformed to the external sexual organs rather than to the sexual glands.

Professor MILES PHILLIPS showed a specimen of contraction ring in the first stage of labour. This was a post-mortem specimen of a uterus containing a foetus at term, showing an internal stricture. It had been obtained from a primigravida of 29, who died unexpectedly whilst recovering from examination under an anaesthetic during a labour which had lasted more than three days. Chloral hydrate, morphine, and scopolamine had been given during the first two days, and nembital (six grains in all) and chloral hydrate during the last ten hours. Oedema

of the glottis and slight chronic renal sclerosis were the only lesions found. There was no obstetrical injury. The foetus, of eight pounds weight, lay as a right occipito-posterior, with the head in the upper pelvic cavity. The ring persisted after death as a horizontal, sharp-edged, crescentic ridge, visible on the inner surface only, exactly opposite the neck of the foetus. It extended round a third only of the circumference of the uterus at this level, and was 17.5 mm. thick at its base, with a flat upper and concave lower surface. The uterine wall above and below was only 4 mm. thick (3 mm. at the cornua), except for a small localized thickening (9 mm.) opposite a depression below the knees of the foetus. The cervix was thinned to 2 mm., and was not quite half dilated. The membranes had been punctured on account of hydramnios when the cervix admitted two fingers. Professor Phillips considered that the contraction ring afforded an explanation of the repeated attacks of colicky pain which had distressed the patient during the last thirty-six hours: in the interests of the foetus they would have been better treated by repeated doses of morphine with atropine.

Mr. OLDFIELD described the following two cases.

1. Wertheim's operation for cancer of the cervix performed during labour.

The patient was aged 31, and a 5-para: she was admitted to St. James' Hospital, Leeds, on June 27th, 1933. She was first seen by Mr. Oldfield thirty-six hours after the onset of labour, on the afternoon of June 28th. Pains were strong and expulsive in character; maternal pulse 110; the head was above the brim, and the child was alive. A hard nodular infiltration of the left posterior part of the cervix was felt. The os was dilated to the size of a five-shilling piece, and the membranes had been ruptured eighteen hours. Examination under ether strongly suggested the diagnosis of carcinoma, and two small portions of the growth were removed for biopsy: this was followed by free haemorrhage, the first of which had occurred during the labour. There had been a slight discharge of blood during November and December, 1932, and in April, 1933. Two hours later, when histology had confirmed the clinical diagnosis, Wertheim's hysterectomy was done. A long skin incision was made, and the uterus everted: Caesarean section was not done. There was no special difficulty except during separation of the left ureter, which was adherent to the growth. Recovery was uneventful. On July 14th the patient was transferred to the radium department of the General Infirmary at Leeds, and received 4,500 milligram-hours of radium in three doses, followed by a course of deep x-ray therapy. She has remained well since. On February 21st, 1934, she had no symptoms, and looked well. At the roof of the vagina was a small area of thickening, and a tight narrow band of tissue anchored this part to the side of the pelvis. There was no ulcer and no bleeding on examination.

2. Menorrhagia cured by splenectomy.

The patient was a girl of 25, who had suffered from menorrhagia for three years and resultant relapsing anaemia. Her menstrual periods usually lasted three weeks. There was no pelvic cause for the bleeding. She had been treated at York, after examination under anaesthesia, with drugs, sera, and injections of whole blood, with little effect. She was admitted to the Hospital for Women at Leeds in August, 1933, and Dr. Hartfall was asked to examine the blood and report. Examination showed a deficiency in platelets, prolonged bleeding time, and bruising on percussion over bony points. A purpuric eruption could be produced by venous congestion. There had never been a purpuric rash or bleeding from other mucous membranes. The spleen was not palpable and there was no family history. Splenectomy was advised, and was done by Lord Moynihan after two blood transfusions. The bleeding time became normal immediately after operation. Within six days the platelet count had risen from under 20,000 to 1,000,000 per cubic millimetre. They then fell to 500,000 and had remained about 400,000 since. A menstrual period of normal amount, lasting four days, occurred in the second week of convalescence. The general condition of the blood improved quickly, and now, nine months after operation, the blood was normal and the patient in perfect health. Since operation she had had short regular periods and no excessive loss.

Mr. Oldfield said that this case emphasized the necessity for a full blood examination in all cases of menorrhagia of obscure aetiology.

Mr. PETER McEWAN read a paper on a study of hysterectomy, with an investigation into the after-histories of 112 cases, the text of which appears at page 574.

CORRESPONDENCE

Sudden Circulatory Failure and Diabetic Coma

SIR,—With reference to the letters of Drs. C. J. Fuller and H. P. Himsworth in the *Journal* of February 17th (p. 305), and of Dr. A. H. Douthwaite (February 24th, p. 353), I would like to make a few observations bearing on this question.

Early in the use of insulin—I think it was in 1923—when I was assistant in the Medical Unit, University College Hospital, I remember treating a female patient brought to the hospital in diabetic coma, in whom treatment with fluids and insulin resulted in recovery from the coma, with, I believe, a cessation of glycosuria and ketonuria. She conversed with me, but her blood pressure failed to rise and the secretion of urine ceased; death occurred abruptly soon afterwards. At the time one considered this a vascular failure, probably vasomotor in origin, due to the patient having been in coma a considerable length of time.

For the past twelve months, at Johns Hopkins Hospital, I have been making observations on cortical adrenal insufficiency in the dog as to the mechanism of the haemoconcentration and circulatory collapse, the results of which I hope to publish shortly. Here the condition appears to be due directly to loss of plasma electrolytes in the urine. This condition is analogous, in many respects, to the condition of "shock" developing in some cases of diabetic acidosis and coma, where a large loss of tissue fluid and electrolytes have occurred in the urine, quite apart from the condition of acidosis. These cases have often been referred to as uraemia and kidney failure, but the condition is dependent largely on peripheral vascular collapse, with decrease in the circulating blood volume and a low blood pressure. There is a stage in diabetic coma, usually late, when giving saline solution intravenously is not sufficient to alleviate the condition by raising the blood pressure and restoring the circulating blood volume, and when all the usual remedial measures have been used, transfusion of whole blood seems to offer the only permanent means of restoration of the volume of the circulating blood. To two articles,¹ which have been published in this country in the last twelve months, I would refer the above correspondents. Therefore one would suggest transfusion of whole blood in the class of case giving the clinical picture described by these correspondents.—I am, etc.,

KENNETH STUART HETZEL,
Thorndyke Memorial Laboratory,
Boston City Hospital

Boston, U.S.A., March 15th.

A Milk Ration for Children

SIR,—Sir Ernest Graham-Little asks whether I "really suggest that the Bill which may come before Parliament as a result of the present agitation for supplying milk to school children should insist upon the milk being of 'certified' quality?" I would reply: No, Sir; but I do seriously suggest that the Children's Minimum Committee should substitute for the words "pure fresh milk" the words "the best milk available." It should be left to the local medical officer of health to advise the local education authorities as to what is the best milk available. The supply to the schools should not be restricted to any one form of milk; for the reason that in one district pasteurized milk might be the best milk available, in

¹ Peters, J. P., Kydd, D. M., and Eisenmann, A. J.: Serum Proteins in Diabetic Acidosis, *Journ. Clin. Invest.*, 1933, xii, 355; and Sheppe, W. M.: The Control of the Circulatory Failure in Diabetic Coma, *West Virginia Med. Journ.*, 1933, xxix, 107.

another district raw certified milk might be the best, or even the only, clean milk available. And I would go further: at present it is often difficult to say what is the best milk in the district, because the choice is often between raw certified milk and doubtfully pasteurized milk. This difficult choice would be obviated if pasteurized certified milk were available. So I really do suggest a memorandum by the Ministry of Health (or a clause in the Bill) to permit the pasteurization of certified milk.

My view is (*British Medical Journal*, November 18th, 1933, p. 945) that if disinterested specialists in hygiene are agreed that raw certified milk is not safe enough it is useless to dispute the point. The question then is: Can raw certified milk be made safe enough by better tests, better methods, etc.? If so, then that is the best course. If not, and in the meantime, the producer of certified milk must be allowed to pasteurize his milk. My argument (*Spectator*, March 9th and 16th, 1934) is that the best way to get healthy children and healthy cows is to buy pasteurized certified milk. I suggest that members of Parliament should insist on the best milk available, because I think it would pay the country. I cannot answer for the Archbishop of York, about the dole, but I appreciate the association. I gather that Sir E. Graham-Little would let the tested herds go. I think that is a bad policy, and not only because I think that it would be grossly unfair to the people who have built up what are admittedly the best herds in the country; but this letter is already too long.

I will only add that I think it is a great pity that Sir E. Graham-Little gave his reference in the *Times* as a "well-known laboratory" instead of the United Dairies laboratory. I should be interested to know whether the zeal of United Dairies for pasteurization extends to the pasteurization of certified milk, or whether they take the view that the country cannot afford to supply school children with certified milk in any form.—I am, etc.,

Wetherby, Yorks, March 25th.

R. L. KITCHING.

Ovulation and Menstruation

SIR,—In the paper on ovulation and menstruation in the *Journal* of January 6th (p. 7) Dr. Wilfred Shaw made scarcely any remark on the work of Ogino of Japan. The correspondents on the same theme in the later issues of the *Journal* mentioned nothing about his work. Ogino's interesting research on menstruation and ovulation, as well as on the period of conception, was highly appreciated by eminent Continental gynaecologists. The monographs introducing his work have already appeared in Holland and the United States.

His fundamental idea was that menstruation is a phenomenon which follows ovulation, not the reverse; therefore the date of ovulation should be calculated back from the succeeding menstruation. He has studied 118 cases of varying menstrual cycle, investigating ovaries during abdominal operations and follicles and endometria, by histological means. He found out definitely that ovulation occurs twelve to sixteen days before the succeeding menses. Professor H. Knaus of Austria came to the same conclusion by endocrinological research; the only point on which he differs is that ovulation occurs fourteen to sixteen days instead of twelve to sixteen days before the succeeding menstruation. Ogino, believing that the human ovum loses its facility of impregnation a few hours after ovulation, proved by clinical statistics that these eleven days before the succeeding menses were absolutely sterile. There is also some sterile period between the preceding menses and the period of ovulation, according to the length of cycle, because the capacity for impregnation

of the human spermatozoon in the female organs probably lasts three days. The existence of this periodical sterility was a great relief to those people who are not allowed to use any mechanical or chemical contraceptive methods, and who want to limit their families.

Ogino proved that the previous conflict of opinion in regard to ovulation was due to the calculation of its date from the preceding menses. He revised the cases in which the dates of ovulation ranged from eleven to thirty-four days after menstruation from the reports of Fraenkel, Ruge, Schröder, Tschirdewahn, etc., and, by bringing these cases into relation with the menses that followed, he succeeded in confirming that in 542 out of 557 cases all these ovulations had occurred between twelve to sixteen days before the subsequent menses. The other fifteen cases could be explained because of the pathological condition of the patient, insufficient data, etc.

The result of Dr. Shaw's investigation that ovulation is restricted to about the fourteenth day after the preceding menses in a twenty-eight days' cycle also supports Ogino's theory. Dr. Shaw believes that *Mittelschmerz* is an unreliable sign as to the rupture of the follicle, but Ogino mentioned in his paper two obvious cases from Tschirdewahn and Ando, proving that *Mittelschmerz* appeared exactly in Ogino's period of ovulation. His papers have been published in the *Zentralblatt für Gynaekologie* (1930, liv, and 1932, lvi).—I am, etc.,

London, N.W.3, March 12th.

DENZABURO KATO.

Teaching Hospitals and Manipulative Treatment

SIR,—No medical man can deny the benefit derived from manipulation in certain cases, and that the general public are demanding this type of treatment more and more. It seems probable that the Bill for the registration of osteopaths will soon become law. This will be an inestimable benefit to those osteopaths who have undergone an extensive training, and who will now, for the first time, be able to distinguish themselves from the much greater number of unqualified practitioners, who are really no more than untrained masseurs. It should be borne in mind that the number of qualified osteopaths who will be able to practise in the British Isles is under one hundred. It is probable that given the inducement of a recognized status many of the unqualified group will undergo training. Medical practitioners will undoubtedly experience a much more formidable competition from this future reinforcement of the ranks of qualified osteopaths. It is essential, therefore, at this stage that the medical profession should turn out doctors conversant with the methods of manipulation.

I suggest that there is room in the physiotherapeutic department of every hospital for the creation of the post of two house-surgeons or clinical assistants, whose work should be to carry out gentle daily manipulative movements to the patients attending the department, as the doctor in charge of the department has no time to carry these out daily. These gentle manipulative movements are quite distinct from those of the passive type. In cases of recent injury, chronic stiff joints from injury, osteo-arthritis, and fibrositic conditions, gentle daily manipulations are as important as massage, diathermy, and faradic contractions. These latter methods prepare the joint for manipulation, and so often this important procedure is entirely omitted. It is not too much to estimate that three-quarters of the patients attending the physiotherapeutic department of each hospital require gentle manipulations daily.

Some will argue that it is waste of time for a recently qualified man to spend six months learning the methods of manipulations. This will not be so, because he will

obtain a sense of touch and a knowledge of the treatment of many medical and surgical conditions which will be invaluable in his work in general practice, and which he would not otherwise come in contact with in his duties as house-surgeon or house-physician. From the various teaching hospitals of the British Isles hundreds of men would be trained annually in the art of manipulation, which, combined with their medical knowledge, would make them far more proficient than the osteopath, besides increasing the value of other physiotherapeutic methods a hundredfold.—I am, etc.,

London, W.1, March 21st.

W. ELTON TUCKER.

Multiple Teeth Extractions

SIR,—During the last few weeks I have twice been called at night to stop haemorrhage from the gums after teeth extractions. One was serious, the gums being torn and the patient having lost a great deal of blood before I saw her, and suffering from shock. In one case ten teeth had been removed, in the other fourteen. In these days, owing to the improvements in giving anaesthetics, longer time is allowed the dentist, and often many teeth are extracted at one sitting. I am writing to suggest that multiple teeth extractions should be treated much more seriously than they are at present. The patient should always be accompanied by a friend, sent home to bed, and given definite instructions as to mouth washes, food, etc. In certain cases the operation would be best done in a nursing home or hospital, the patient staying the night.—I am, etc.,

Kensington, W., March 25th.

HOWARD M. STRATFORD.

Diathermy in the Treatment of Essential Hypertension

SIR,—I have read with great interest Dr. Gunewardene's excellent article (*British Medical Journal*, December 16th, 1933, p. 1114) on the treatment and control of essential hypertension by electrical stimulation of the skeletal muscles. There is, however, one remark to which I would take exception, and which might lead practitioners to abandon a very valuable form of treatment. I refer to his remarks on diathermy. Concerning diathermy he states: "I was never able to convince myself that pressure was reduced to an extent which could not be explained by the simultaneously ordered rest, in spite of Clifford Allbutt's statement nine years ago that 'd'arsonvalization by the auto-condensation method is the most valuable immediate aid we possess for hyperpiesia.'"

I am glad to say that I can endorse Clifford Allbutt's statement, and have found diathermy the greatest use in cases of hypertension during the last five years, despite the fact that rest is never ordered. It can only be suggested to Dr. Gunewardene that either his apparatus was not powerful enough to produce the desired effect or the frequency was unsuitable. I consider the latter to be of considerable importance, and by making a change in the frequency of the machine used I am getting better results now than I was two years ago, when using a higher frequency. Again, the condenser couch and the thickness of the dielectric are important factors. Of course, it goes without saying that the sources of infection must be diligently searched for and eliminated, and the mode of living investigated and corrected if necessary. If these points are attended to and suitable apparatus used, good results can be obtained not only in recent cases but also in long-standing ones.—I am, etc.,

Christchurch, New Zealand.

D.M.R.E. Cantab.

Regarding the Nature of Cytost

SIR,—Some time ago my attention was called to a book by Fenton B. Turck,¹ in which a peculiar biologically active substance, which the author called "cytost," was described. Dr. Turck's principal thesis is that anabolic and catabolic processes, both normal and pathological, are governed by this endocellular substance; or, to use his own words "... that the apparent stimulating and repressive activities of various physical and chemical agents, as well as the pathological changes which they induce, are due to a common cause—namely, the release by the cells themselves of a substance capable of modifying cellular activity." The author has termed this substance "cytost." A little later the following statement is made: "As will be shown in our subsequent discussion it is improbable that cytost and histamine are identical."

Preparations of cytost are only supposed to produce their action on homologous animals—for example, if a tissue extract of cytost is prepared from the muscle of a dog it will be found to be an extremely active substance when administered to another dog, but will be ineffective if it is administered to a cat or a monkey. The method of preparation of the extract is very simple. It consists essentially of a saline extract of autolysed tissue, which is later passed through a Berkefeld filter. Such an extract will contain all the water-soluble metabolites originally present in the tissue, and a number of others resulting from autolysis. I have investigated the actions of such extracts, and have been unable to reproduce any of the startling results described by Dr. Turck. The only action which I have been able to demonstrate is a histamine action which is equally effective on any animal. The "subsequent discussion," which is supposed, to demonstrate the differences between cytost and histamine, cannot be found in the book. In addition to the histamine content of these crude extracts there will be present a certain amount of adenosine, acetylcholine, propionylcholine, and butyrylcholine, all being substances capable of producing the acetylcholine response.—I am, etc.,

University of Alberta, Canada.

DAVID R. CLINENKO.

Treatment of Arthritis

SIR,—I was much interested to read Dr. C. W. Buckley's article on the causes and treatment of arthritis, in your issue of March 17th (p. 469), and particularly so in his remarks on vaccine therapy in the treatment of this disease. It is very difficult indeed to have a thorough consensus of opinion on the result of vaccine therapy, as there are so many factors which operate against a good result.

1. Most bacteriologists have their own special methods of the preparation of cultures.

2. The taking of specimens, etc., is usually left to the general practitioner, who may be unfamiliar with bacteriological technique.

3. The specimens are often delayed in the post for more than twelve hours before being put in the incubator, when, to ensure the proper growth, they should be put into the incubator immediately after being taken from the patient; and if they are to be sent a long distance they should be sent in a vacuum flask at body temperature.

4. Again, the bacteriologist is not familiar with the clinical side of the case, and this puts him in the position that he is not able to judge accurately the doses required, and to gauge the first dose is just as important as the most delicate surgical technique in the treatment of disease, because the failure of this is very well demonstrated in Dr. Buckley's statement "that there have been more cripples than cures

following the injudicious, un instructed, and often haphazard administration of a remedy which, with skill and care, has sometimes proved of great value." At least 75 per cent. of good results is my experience in the treatment of this condition for the last ten years.

5. Again, the immunologist or the clinician should be just as familiar with the bacteriological side: in other words, it is essential for good results in vaccine therapy to bring the laboratory to the bedside.

6. As regards the technique itself, it is necessary to isolate and incorporate in the vaccine the causative micro-organism, because the vaccine treatment of arthritis is just as specific as the typhoid vaccine.

The school of thought which holds that the good result from vaccine therapy is due to protein shock will be very shocked themselves when they contemplate how much protein is in a suspension of 1/16 million streptococcus, which is the dose one often begins with.—I am, etc.,

London, W., March 19th.

M. R. BRADY, M.D.

Hereditary Scoliosis

SIR,—Referring to the article by Dr. Hugh Garland, published on February 24th (p. 328), and the questions asked by Dr. Thomas McKee in your issue of March 17th (p. 507), I am of the opinion that the malformation described is indubitably of an acquired character. Genetically, such a condition is most unlikely, and there are no embryonic derangements which would support such a theory. With a practice in an industrial area, and in a long survey of patients, I have observed kyphosis very marked in the grandmothers, due to the nature of their work, which necessitated constant bending. This bending, continued for years, caused constant pressure upon the anterior portions of the bodies of the vertebrae and the intervening intervertebral disks, with consequent atrophy and absorption, producing the characteristic "hump-back," so common years ago among certain classes of working women. This being a time when the birth rate was very high, these women had numerous offspring. The elder children of the families had to nurse and attend to the younger members while the mothers were at work, and, as perambulators were then a luxury, the little "mothers" carried the children in their arms for hours. Meanwhile, lack of suitable and adequate nourishment, causing undue softness of their bones, resulted in the production of malformations of the spine in these members of the second generation. In these one observed both kyphosis and scoliosis, but scoliosis was often the more marked, again due to uneven pressure of the vertebral column.

Now one comes to the third generation, which is the present one. If the condition were hereditary we should expect the malformation to be still more marked; but, as a matter of fact, among these children of the same families, it is practically absent, or, at any rate, not a noticeable deformity. Proofs of this can be demonstrated daily. This is brought about by the improved conditions of the present generation. Even the poorest child to-day is better off than most children of the last generation, by reason of education, improved social conditions, etc. The limitation of families has relieved the elder ones of their burden, and allows more of the necessities of life for all. Food with a high calcium and vitamin content is more generally consumed, while any deficiency in quality or quantity of nourishment is remedied at the schools and welfare centres, so that the child is sure of adequate bone-forming elements, while the schools also encourage good postures. Thus perfect growth is being ensured, and the acquired malformations are slowly but surely being eradicated, to the benefit of all.—I am, etc.,

Birmingham, March 20th.

CLEMENT BELCHER.

¹ Turck, Fenton B.: *The Action of the Living Cell*. New York. 1933. Reviewed in the *Journal* of June 17th, 1933, p. 1056.

Hypochondriasis, Labour, and Analgesia

SIR,—I have read, with mixed feelings, Dr. J. W. Hamilton's letter in your issue of March 17th (p. 505). Is it not time that the medical profession disabused itself of the idea that labour pains are a species of female neurosis? It is highly ridiculous for us, firmly protected by bars of unassailable immunity, to dismiss thus smilingly and blandly the woman's claim and right to a painless labour. There is nothing salutary to mother or child in a painful labour. All this nonsense emanates from men, and women are strangely silent thereon.

Has it occurred to Dr. Hamilton that *pari passu* with the deplorable degeneration of women, which he laments, a generation of men has arisen incapable of having a tooth extracted without anaesthesia, incapable of having a limb amputated by the old methods? It is right and proper that these things should be done under anaesthesia of some sort, because men may be called on to suffer therefrom! The edentulous female does not criticize the male mental attitude towards a visit to the dentist, nor do women deny men the right to a painless prostatectomy, from which latter pain they are as immune as the man is from parturient pangs. A woman's first confinement is often a very painful and dreadful experience, productive of lasting psychological traumata which tend to increase the difficulties of her subsequent easier labours. A painless first confinement would avoid all this. Surely a woman is entitled to "fair play."

Doubtless many have now received, as I have, a folder with a picture of Thomas Sydenham. Underneath was written "*Nollem esse medicus sine opio.*"—I am, etc.,

Blackheath, March 20th.

WILLIAM G. WATSON.

Colonic Irrigation

SIR,—May I add to the observations of the chairman of the Education Committee of the College of Nursing, in the *Journal* of March 10th (p. 459), that the practice of what is popularly known as "colonic irrigation" is one that calls for all the knowledge and acumen that can be applied to it, and, further, is one the responsibility for the results of which cannot be delegated to anyone?

As one who has himself practised irrigation for a number of years, and regularly employs a whole-time nurse to do for him what, for one reason or another, he is unable to do for himself, and has thereby learnt at first hand, as well as through the medium of the nurse, something of its difficulties and dangers, I feel in a position to state that one great, if not the greatest, danger is that of delegation, which is the basic factor underlying the point at issue in the letter referred to. This reflects in no way on the probity or skill of the nurse to whom it may be delegated, but on the fact that, unless the medical man in charge of a case is able to be present to note what is to be learnt in the matter of diagnosis that irrigation provides, to watch the changes in the degree of digestion of food ingested, the changing amount and character of catarrhal mucus washed out in progressive stages, and so on, or has a delegate specially trained to observe these objective signs for him, he must be completely at a loss to know how to point the direction of further treatment or to know what real progress is being made, for the subjective feelings of well-being usually experienced by a patient after its administration are wholly illusory, and misleading as a guide to progress. Moreover, there are other more immediate dangers to the patient arising from injudicious lavage performed without proper medical control.

It follows, then, that routine irrigation is not a rational procedure, by whomsoever it may be performed. None the

less, irrigation is invaluable as providing positive first-hand clinical evidence of the degree and nature of intestinal failure that cannot be as accurately gauged in any other way, and indispensable as a first-aid measure in that one condition in which intestinal block thrusts its warning note. It is very necessary, therefore, that none but qualified nurses, who naturally will only undertake work under medical authority, should be thoroughly trained to observe, record, and appreciate the niceties of the operation, so as to be able to state the facts intelligibly that the medical man may interpret them correctly; and that instruction in technique include not only a recital of the difficulties and dangers to be met with, but insistence on its practical value to the medical attendant when properly performed and recorded, as the bedrock upon which the procedure stands.—I am, etc.,

Nice, March 16th.

F. A. HORT.

SIR,—With reference to the recent letters on colonic irrigation I note that Miss MacManus, in your issue of March 10th, states that "the Education Committee of the College of Nursing feels that this treatment should be carried out by a trained nurse, working under the direction of a doctor." I agree with this opinion, and beg to differ from Mr. Elmslie, who states that "it is really a question of the convenience of organization and of the patient." I maintain that it is essentially a question of the welfare of the patient, and a question of far-reaching importance, too. Masseuses and bath attendants may have an adequate knowledge and experience for their own work, but colonic irrigation comes under an entirely different category. If colonic irrigation is allowed to come within the scope of a masseuse, or bath attendant, the next inevitable step will be for the masseuse to be expected to undertake nasal feeding, rectal feeding, gastric lavage, test meals, vaginal douching, and bladder washouts—treatments which are safer in the hands of a trained nurse.—I am, etc.,

N. I. LANCKENAU, M.D., B.S.

Examiner for the Chartered Society of
Massage and Medical Gymnastics.

London, W.C.1, March 21st.

SIR,—With reference to the question at present under discussion as to whether a trained nurse or a trained masseuse should undertake treatment by colonic lavage, it has been suggested that some additional experience is necessary in either case.

Over forty members of the Chartered Society of Massage and Medical Gymnastics, some of whom are nurses, are employed on the staff of this clinic, and colonic lavage is constantly prescribed by the physicians. It has been found that certain instruction in the special technique required is necessary for the trained nurses; one or two demonstrations are, however, all that they require in order to become proficient. In passing the rectal tube, in excluding air, in keeping the patient dry, and in maintaining the fluid at the correct temperature and pressure they are already skilled. The whole of their past training has made them familiar with this type of work, and enables them to undertake it with confidence. They are trained by years of routine examination of stools to recognize and describe the results of their treatment, and to report any abnormality at once to the physician. In the case of one or two masseuses who were allowed to give colonic lavage it was found that they needed detailed instruction and much supervision before they acquired the art of manipulating the tube and fluid satisfactorily. They themselves realized that they were quite unfitted to report on the results, having never seen any of the abnormalities for which they were instructed to watch.

Although it may be possible to provide facilities for members of the Chartered Society of Massage and Medical Gymnastics to receive instruction and to gain experience in this subject, it would still seem undesirable for their training to be lengthened and their syllabus extended to include a form of treatment in which the nurse is, by general training, so much more fitted to specialize.—I am, etc.,

W. M. McALLISTER,

Matron, British Red Cross Society's
Clinic for Rheumatism.

London, N.W.1, March 21st.

Pathogenesis of Cancer

SIR,—One aspect of the pathogenesis of cancer has not been alluded to. The late Sir Henry Butlin said that the scrotum was most resistant to cancer, and only succumbed to it under the irritation of soot (+ mule oil). Other organs also have their specific cancer-producing irritants: the bladder—aniline; the tongue—syphilis; the skin—tar, paraffin, and x rays. Workers in arsenic die frequently of cancer of the lungs. In this connexion I noticed in my colliery practice that cancer of the rectum was much more prevalent than any other form of cancer; all my cases were males and all but one colliers. I wonder if other colliery surgeons have had a similar experience.

I think Sir Henry Butlin suggested that there was not one definite material (*materies morbi*) cause of cancer, but that cancer was the result of the interaction of the secretions of the area or organ affected, with its specific irritant. Soot and aniline do not figure as causes of cancer of the rectum, tongue, or stomach, but of the scrotum and bladder; a similar restriction applies, perhaps, to x rays, tar, and paraffin. That the local secretion may yield a contributory factor may be one reason for the rarity of cancer in the male breast. This aspect makes the problem a problem of biochemistry.

As to treatment, other than surgical or radium, what is urgently needed is a "lead from Nature," such as Coley's genius took advantage of. Has Professor Blair-Bell's treatment sprung from the same source? Many years ago the late Dr. Beatson claimed for his operation a similar sanction. Nowadays we rarely read of "spontaneous cures of cancer." The late Sir William Bennett wrote "that there were very few surgeons of many years' standing who had not seen at least one or more cases of spontaneous cure of cancer." Is that true to-day? I think I read in the *Clinical Journal*, twenty or more years ago, an article by the late Mr. Bruce-Clark on a case of arrest of cancer, and Sir Henry Butlin stated his belief in the arrest of cancer in the cervical glands left after removal of the tongue. Such cases—"spontaneous cure" or "arrest of cancer"—if they occur to-day, should be examined most conscientiously, I think, by acute observers at our hospitals and clinics, as well as by the general practitioner, to glean some hints of Nature's methods of curing or arresting the disease.—I am, etc.,

M.D.

March 14th.

The Tuberculosis Problem

SIR,—Although a comparative newcomer to the ranks of those in search of the tuberculosis philosopher's stone, may I submit the following text?

It is being stated authoritatively that (a) conjugal tuberculosis is rare; (b) adult infection and reinfection is impossible; (c) the segregation of + and - sputum cases is unnecessary; (d) healthy workers in institutions for the tuberculous are in no danger; and that (e) tuberculosis constitutes no problem in the school child. These truntings harmonize badly with bruitings anent "sources of infection" and "percentage of contacts

found tuberculous," etc. Little wonder is it that a medical man in general practice has written of the tuberculosis officer as "dabbling a finger on a patient's chest" and inscribing a "no-evidence-of-active-tuberculosis chit." The T.O. suffers the explicable contempt of the general practitioner, while celestial voices call for more contact examinations and mundane voices call for more economical use of radiology. As if any "tuberculosis expert" could ordinarily certify as non-tuberculous a case referred to him without x -ray examination. If he does, can he say that the patient, if exposed to infection, will not develop the disease in six months or five years?

The greater the proportion of contacts found tuberculous the more inefficient is the anti-tuberculosis scheme. This follows because there must be a case notified before contacts come into existence (on paper). The longer a case is in an infective state before notification the more heavily infected the contacts become, and the more likely they are to have demonstrable disease. Is tuberculosis an infectious disease caused by the tubercle bacillus? If it is, why not treat it like other diseases of this nature, and not attempt to cloak the communicable aspect, even if we admit that the incubation period may be infinitely short or infinitely long? After fifty years of the practice of preventive methods we are scarcely any nearer an ideal than when Koch first demonstrated the transmission of infection. The relative who so often says, "It can't be, doctor; there is none of it in our family," is not so befogged as the tuberculosis officer who has to make answer to this. Indeed, in connexion with this and other questions the T.O. might well be described as a very worried, prematurely aged man with a lot of writing to do. It sometimes happens that the contact found tuberculous is considered to be the infecting agent from which the notified case has derived the disease. Macaulay would have liked the opportunity that such instances give for making antitheses. It is also noted that the patient who complains most is not seldom not actively tuberculous, while the patient who insists that he feels quite well often has advanced disease. The bearing of this on the possibility of large numbers of carriers distributing infection unknowingly is obvious, and it is possible that the bulk of cases where no source of infection is known have arisen from such carriers, directly or indirectly.

Universality of infection is the gospel of some, denied by others. Those who apply the intracutaneous tuberculin test are usually surprised to discover an appreciable number of negative reactors. It is probable that these negative reactors have either never been in contact with infection or have received such minimal doses that infection has never been accomplished. The significance of the presence of negative reactors is realized in some of our hospitals where children and others are admitted for observation regarding the presence or absence of tuberculosis. The possibilities underlying the application of the test to the general population, or a section of it, do not appear to be appreciated. It is probable that the lack of facilities to-day for transmission of the disease, which is due to the control of infectious material in the home and the isolation of large numbers of infective patients in institutions over a long period, is the cause of the lowered incidence rate of the disease and the decrease in mortality figures. If the question of infectivity is controversial, as it seems to be at the present time, then a rise in both rates is to be expected owing to a natural tendency to slacken the grip on the problem. New plans will have to be adopted to put into application old and new methods based on the acceptance of the facts relating to the bacterial nature and infectiousness of the disease.

It must be true that anybody and everybody may become infected by the tubercle bacillus, and that demonstrable disease depends on the mass of infection and period and mode of contact, combined with lowered resistance from any cause. Childhood tuberculosis is due to first infection, and depends in type on the mode of ingress of the bacillus. Adult tuberculosis may be due to reactivation of a primary focus due to lowered resistance or to superimposed infection, or, indeed, to primary

infection if the individual has not been previously exposed. The tubercle bacillus is no respecter of persons, and infection may, and does usually, occur without obvious illness. A cheap, reliable, and easily applicable method for finding out when this happens, and possibly whence the infection comes, would be invaluable. The intracutaneous tuberculin test as devised by Mantoux is easily applied, reliable, and not dangerous. It is a quarter of a century old.

Now if it were possible for the powers that be to get rid of their complexes regarding dispensary attendances and contact examinations they could devote some of the available machinery to making a survey of the amount and distribution of tuberculous infection in any area. This could be done by applying the intracutaneous test to everybody in a given district or in several schools, or even in one school. Negative reactors could be re-tested six-monthly to find out if and when infection occurs. Positive reactors could be further investigated for cases of active disease and possible source of infection. This method might bring to light many unknown sources of infection at present acting as carriers of the bacillus. Incidentally, it is a more scientific procedure to discover an unsuspected case of the disease, and by its removal or supervision prevent the continued dangerous infection of its contacts, than to wait for a case to be notified and write off as non-tuberculous those contacts who are not obviously diseased. Surely the method at present in existence savours of "locking the stable door after the steed is stolen." The useless physical examination of contacts and children as practised to-day is one of the sacrifices that a conscientious tuberculosis officer has to offer on the altar of tradition.

A survey of the amount of tuberculous infection present in a community must be possible on the lines suggested above. Elaboration is necessary, and such a scheme would of necessity need sponsoring by the powers that be. In one or two areas in America where such methods are in existence sceptics have been surprised at the results obtained. The possibilities of adding to our rather meagre knowledge of the local and general epidemiology of the disease are boundless. The finding of a source of infection before the individual becomes ill enough to seek treatment voluntarily would be a true application of the science of preventive medicine.—I am, etc.,

London, S.E.10, March 12th.

F. R. WALDRON.

Testimonial to Professor R. W. Reid

SIR,—In response to a widely expressed desire that his colleagues, former pupils, and friends should be given an opportunity of marking their appreciation of the long and distinguished services rendered by Professor R. W. Reid, M.D., LL.D., F.R.C.S., to the University of Aberdeen, a committee, consisting of representatives of the University Court, the Senatus, former students, and others, has been formed to arrange for a testimonial. It is proposed that the testimonial should take the form of a fund, "The Reid Fund," the revenue of which should be utilized for the foundation of a lectureship in anthropology, including the cultural and sociological aspects of the subject. The committee feels that this would be a fitting monument to Professor Reid's able and devoted work for Aberdeen University, and for the science of anatomy, which has had so much influence on the many hundreds of students who passed through the anatomy department during the years 1889 to 1925. Twenty-eight years ago he instituted the Anthropological Museum, and all along has acted as its honorary curator. By his zeal he has not only created and catalogued a valuable museum—a great teaching asset to the University—but has stimulated and done much to promote the interests of anthropology, particularly in relation to the prehistoric peoples of the North of Scotland.

The committee is confident that colleagues, former pupils, friends, and others interested in the advancement

of the study of anthropology will wish to be associated with this testimonial. Contributions to the fund should be sent to the honorary treasurer, Mr. H. J. Butchart, D.S.O., B.L., Secretary, The University, Aberdeen.—We are, etc.,

MESTON,
Chancellor of the University of
Aberdeen.

WALTER ELLIOT,
Rector and Chairman of the
University Court.

GEORGE ADAM SMITH,
Principal and Chairman of the
Senatus Academicus.

University of Aberdeen,
March 22nd.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Dr. O. A. Trowell has been appointed university demonstrator in physiology for three years from October 1st, 1934, and Dr. H. N. Green university demonstrator in pathology for three years from April 1st, 1934.

Alice Barbara Field (Newnham College) has kept the Act as required for the degree of M.B.

UNIVERSITY OF LONDON

At a meeting of the Senate, on March 21st, Professor Karl Pearson, LL.D., F.R.S., was appointed Heath Clark Lecturer for 1934.

UNIVERSITY OF LEEDS

The following candidates have been approved at the examinations indicated:

M.D.—E. Gledhill (with distinction), S. Ross.
FINAL M.B., CH.B.—(Part I): A. J. E. Barlow, T. M. Boyle, Julia M. Brown, D. F. Cameron, G. Clarke, G. A. Collinson, S. C. Crystal, W. G. L. Flather, Irene Haslegrave, J. Holden, E. H. Kitching, E. F. Lai, H. T. Levi, D. G. Liveredge, A. E. Penn, T. W. Percival, F. Reid, H. Silman, R. G. Smithson, H. E. Steward, E. H. Tomlin, C. C. N. Vass. (Part II): E. C. Allibone, J. Benn, D. Bickler, G. Cohda, J. H. Crawford, D. H. Drake, F. H. B. Fuller, H. W. Gothard, J. C. Hutchinson, M. B. Khan, N. Lissimore, W. Lomax, O. C. Lord, L. Nagley, A. B. Raper, R. T. Rushton, H. S. Shucksmith, A. Smith, D. Thackray, G. N. Watson, W. Zemsky. (Part III): H. S. Shucksmith, J. E. C. Allibone, G. N. Watson, J. Benn, D. Bickler, G. Cohda, J. H. Crawford, D. H. Drake, F. H. B. Fuller, H. W. Gothard, J. C. Hutchinson, M. B. Khan, N. Lissimore, W. Lomax, O. C. Lord, L. Nagley, A. B. Raper, R. T. Rushton, A. Smith.
DIPLOMA IN PSYCHOLOGICAL MEDICINE.—F. S. Esler, J. S. Johnson.

* First-class honours. † Second-class honours.

The following awards have been made: Infirmary Scholarship and Littlewood Prize: I. R. Gray. Scattergood Prize: J. C. Hutchinson. Hardwick Prize and McGill Prize: divided between A. B. Raper and H. S. Shucksmith. Edward Ward Memorial Prize: H. S. Shucksmith.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—(Part A): T. N. Fegarty, J. W. H. Foy, S. K. Sahay.
D.P.H. (Part I): T. L. Hughes, H. V. M. Jones, J. A. Jones, F. Langford, E. R. Smith, E. Taylor, V. J. Woodward.
DIPLOMA IN TROPICAL MEDICINE.—A. Ahmed, E. S. Amzalak, A. R. Arulpragasam, J. J. Bransome, P. Y. Chang, F. R. Craddock, A. C. Edwards, T. Foulds, I. H. B. Ghosh, B. A. Hamid, W. Hughes, J. R. Innes, C. C. Ling, J. H. McElroy, J. S. McMillan, T. A. Maloué, P. J. Purcell, K. S. Tay, Banco V. Vakil.
DIPLOMA IN TROPICAL HYGIENE.—N. E. W. Anderson, V. B. Athavale, L. C. Feng, L. P. Greson, S. L. A. Manuwa, C. W. A. de Silva.

* Recommended for the Milne Medal.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly business meeting of the College, held on March 2nd, the following resolution was unanimously adopted:

That this College is of opinion that foreign graduates should not, under any circumstances, be admitted to the final examination until they have first satisfied the examiners of their knowledge of English and of having spent at least three years in clinical study in these countries.

Medico-Legal

THE DUTIES OF THE MEDICAL WITNESS.—III

THE IMPORTANCE OF IMPARTIALITY*

Every medical witness should, for the honour of his profession, aim at impartiality. Apart from their great skill and experience, the chief characteristic of the well-known expert witnesses is their impartial attitude. They regard themselves almost as officers of the court, and hold it their duty to assist in the discovery of truth and the administration of justice, no matter which side may be found to be in the wrong. They are not in the least ashamed to confess ignorance on any particular point; they are not perturbed if their evidence appears to favour the other side more than their own. They are an indispensable help to the court, and do as much as any other doctor to make the public respect the medical profession. Every medical witness should model his attitude on that of such men. Nothing does the profession more harm than the sight, a distressingly common one, of three medical men going into the witness-box on each side in a motor accident case and flatly contradicting each other, giving the impression that they intend their evidence to support the case of the party who has called them.

It is difficult to give medical evidence well, and it would be unjust to assume that many medical witnesses take sides from lack of scruple. Medicine is far from an exact science, and it is always possible, except in the presence of the most obvious injuries, to take either a pessimistic or an optimistic view. Most of the doctors who give evidence in civil actions concerning injury are behaving in a perfectly honest way, but, owing to the infinite possibilities of interpretation of the evidence, both sides are always able to get a sufficiency of doctors to support their respective points of view. Bias is a very human failing and almost impossible to avoid, and under a system by which a medical man is employed and paid by one side it is hardly surprising that he should unconsciously select the aspects of the case which are more favourable to that side. This is unfortunately true in practice, as a visit to the county court will demonstrate. When one of the medical staff of the injured man's hospital happens to be called, his evidence is often conspicuously more valuable than that of the doctors who have examined the injured man on behalf of one or other side, because he is probably the only doctor who approaches the matter with an absolutely unbiased mind.

It would also be unfair to disregard another important factor: if a panel doctor goes into the box in a compensation case and gives evidence against one of his patients, his practice may suffer for his honesty. What is more natural, therefore, than that he should insist on keeping out of the proceedings unless his evidence is likely to be favourable to his patient? Yet another factor which tends to create a perfectly innocent bias in the doctor's mind is that in many injury cases the man's complaints of pain under various conditions of posture and manipulation are very important and, in some cases, are practically the only indications of his condition. If the doctor is sympathetic, these complaints will tell one story; if he is not, they will tell another. Each doctor is speaking the truth as it appears to him, and yet his evidence almost entirely contradicts that of the other.

Another weakness of many medical witnesses is that, having once formed a particular view of a case, they henceforth inevitably regard the case from that point of view, and frame their evidence in the way which they feel will best establish it. This is the type of witness who is most likely to come to grief under cross-examination, because he is almost certain, in his efforts to prove his opinion right, to say more than he can vouch for and to be compelled to admit that he is not, in fact, so sure

as at first he said he was. There is also the unfortunate fact that the qualities which constitute a valuable witness in the eyes of counsel appearing for one of the parties are by no means those which are most highly esteemed by a judge or a medical man.

A member of the Bar once won a slashing victory in a compensation case. He was appearing for an insurance company whose assured was the employer of a workman who had ruptured himself. The workman claimed compensation for total incapacity on the ground that his hernia was still persisting. The doctor consulted by the insurance company thought otherwise. Counsel spoke loud in the praises of his medical witness, who, he declared, had largely won the case for them. "He gave evidence magnificently," counsel narrated. "None of the usual qualification about 'I could not see any evidence of persisting hernia'; he said 'There was no hernia,' and when So-and-so on the other side tried to shake him, he went on saying 'There was no hernia.' That is the kind of witness one wants."

This illustrates the melancholy fact that the scientific attitude, which knows that its evidence for the plainest of facts is at the best dubious and which in order to be honest must be tentative, is a constant source of anxiety and irritation to a tribunal which is trying to arrive at certainty. A dogmatic statement by a medical witness that the facts are so-and-so, especially when there is a good deal of evidence to support it, comes like a vigorous and refreshing breeze into what must seem a fog of speculation. Nevertheless, as every medical and scientific man knows, the cases in which a medical witness can make a definite categorical statement of this kind without departing from the ideal of speaking, according to his conscience, nothing but the truth, are so few as to be almost negligible.

COMING TO COURT

The witness is told a day, time, and place for the hearing, but neither he nor anyone else can tell how long the hearing is going to take. He should therefore be prepared to give up not only the named day but the next as well, and make provisional arrangements for someone to look after his work until he is free. An inquest or police court case is usually either finished on the first day or adjourned for a number of days; a county court case is usually finished on the same day; but a trial or civil action before assizes or in the High Court can well go on to a second day or even longer. "New Procedure" cases offer more hope of a quick finish than actions before a jury. The witness should see the counsel who is representing the party calling him, and persuade him to call him as early as possible and to ask the judge to release him as soon as he has given his evidence.

The doctor should arrive punctually. He may be io time to give his evidence even if he appears an hour, two hours, or half a day late, but he is taking a risk of being severely reprimanded, if not punished, by the judge, and he will make himself very unpopular with solicitors and counsel, who are usually in an anxious state which the absence of a witness intensifies alarmingly. If it is necessary for him to hear the evidence of the other witnesses in order to give an opinion on it, he must arrive before the case is called. In any event, the work goes forward much more smoothly if everyone is there and anything that has to be said between lawyers and witnesses can be said with plenty of time in hand. If the witness knows the solicitor and lives near the court, he may be able to arrange to keep in touch by telephone, so that he can carry on with his own work until shortly before his presence is actually wanted. When he is starting for the court, let him be certain that he is taking with him all the documents he needs, including the memoranda, notes, bones, models, and anything else that he intends to use in the witness-box.

IN THE WITNESS-BOX

When the precepts of all the authorities are digested they amount roughly to the following. Have the subject-matter clear in your mind, and never let your mind wander. In Lord Riddell's words: "He who vegetates

* The first of this series of five articles by a legal correspondent appeared on March 3rd (p. 407), and the second on March 17th (p. 508).

in the witness-box is lost." Listen to counsel's question and make sure you understand it. Answer in non-technical language. Avoid exaggeration or committing yourself to something which you do not really know. Treat counsel for both sides alike. Do not argue with counsel, and, no matter how much he annoys you, never lose your temper.

The doctor who is used to giving evidence in court will probably not need such elementary advice. The doctor who is not used to the witness-box will probably be so frightened that as soon as his name is called he will forget any advice he may have memorized. Nevertheless, a doctor who studies carefully the cardinal rules of the work is bound to assimilate something of the essential attitude of which all maxims are an expression. He will find no better instruction than in Taylor's *Medical Jurisprudence*, vol. i. As soon as he enters the witness-box the witness takes the oath. The form is printed on a card fixed to the front of the box, and he is fully instructed by the usher. He need not kiss the Testament, and, as Taylor points out, it is advisable on every ground not to do so. It is sufficient to hold the book in the right hand, or even to raise the right hand, so long as the witness recites the prescribed words. A witness who objects on conscientious grounds to taking an oath (for example, a Quaker, a Moravian, or an atheist) may be allowed to make an affirmation having the same validity as an oath.

The first piece of advice, to have the subject-matter clear in his mind, is really kept before the witness comes to court at all. He should have decided in every detail what he considers to be the truth of the whole matter, and the manner and language in which he shall present that truth, and should have tested his evidence by a sparring-match with a friendly cross-examiner, and his language by conversation with a layman. When he goes into the box he must follow a rule which really is the corollary of this first piece of advice, and that is to carry out resolutely what he has decided to do. He has formed an honest and unbiased opinion; he should then stick to it tenaciously, even obstinately, in the face of the adversary. To be unbiased and impartial it is not necessary to agree with the suggestions that cross-examining counsel urges in opposition to the witness's considered opinion, or even to admit that there may be some truth in them. The term "adversary" is not out of place, however little the witness identifies himself with the side who has called him. Counsel for the other side—very properly, for it is his job—does identify himself with his side. He is strongly partial, and he takes the view "Whoever is not for me is against me." The medical man, therefore, battles with cross-examining counsel to uphold the view which he has formed as an impartial witness. When he realizes that his work in the witness-box, as far as cross-examination is concerned, is in the nature of a contest—a clean and friendly one, but none the less a fight—he will see that all the rules which the authorities on medical jurisprudence have evolved for him are much the same as the rules which would guide him if he were competing in a tennis or boxing tournament. Counsel for his own side will probably treat him fairly gently, but counsel for the other side may assail him with energy and craft, and he must keep his wits about him and, so to say, keep on his feet, in order that he may come out of the witness-box with credit, having told the truth as he has seen it and not as counsel for the other side has suggested it.

First of all, counsel for his own side will draw out the evidence in chief: the witness's account of the facts, his opinions on those facts, and perhaps his views on the evidence which he has heard other witnesses give. Counsel will do this in such a way that the witness's evidence will appear as favourable as possible to his side. This is his duty, and by the practice of the court the witness is for the time being in his hands. The doctor should remember this and confine himself—at any rate until counsel has finished—to answering counsel's question's without trying to determine for himself the order in which the evidence shall be presented. If he appre-

ciates the part allotted to him in this operation he will save the court and himself a good deal of time and trouble. He must attend carefully to the questions which counsel puts, and give to them the best answers he can, addressing himself to the judge and jury, who are most concerned with the answer, in a clear voice. If he wishes to address the judge, he uses the term "My Lord" or "Your Lordship" in the High Court or at assizes, and "Your Honour" in the county court; he will call a magistrate "Your Worship" and a coroner "Mr. Coroner" or "Sir." He will save the court, not to mention the reporters, much trouble if he remembers to speak up. He must avoid lecturing the court, but if the question demands answer by a lengthy statement the witness should observe whether the judge is taking down the evidence in longhand; if so, he should dictate the statement in sentences of convenient length, waiting between each until he sees the judge's pen stop. If counsel reads to him an extract from a document, in order perhaps to ask his opinion on the passage, the witness should ask counsel to let him see the document before he commits himself to a reply. It is just possible that if counsel had started the quotation a little earlier or finished it a little later the sense of the question and answer might have been quite different.

Let the medical witness be most careful not to guess, exaggerate, or say anything of which he is not absolutely certain. Counsel, in his eagerness to do the best he can for his side, may try to flatter his witness into giving opinions on matters which are not properly within his scope.

Sir William Willcox¹ gives a good example of how a witness should behave in this situation. Sir Edward Marshall Hall once asked a medical man to give his opinion concerning statistics of death from diphtheria before and after treatment with antitoxin. The doctor said: "It is not my special department. I am not an expert on this matter, and I should prefer not to answer these questions." The judge quite rightly supported this witness, and the evidence on the point was left for other doctors who had made a special study of the subject. If that witness had been indiscreet enough to express a wrong opinion, it would have been put to each of the better-qualified witnesses in turn and have been contradicted, a procedure damaging to the professional dignity of the first witness.

(To be continued)

The Services

Colonel H. F. Humphreys, O.B.E., M.C., T.A., has been appointed Honorary Physician to the King, vice Colonel G. L. Thornton, M.C., T.A.

Colonel A. R. Moodie, T.D., has been appointed Honorary Surgeon to the King, vice Colonel C. L. Isaac, T.D. T.A. (ret.).

AUXILIARY R.A.M.C. FUNDS

The annual meeting of the members of the Auxiliary R.A.M.C. Funds will be held at 5.15 p.m. on Friday, April 13th, at 11, Chandos Street, Cavendish Square, W., when the annual report and financial statement for the year ended December 31st, 1933, will be presented and the officers and committee for the current year elected.

NAVAL MEDICAL COMPASSIONATE FUND

A meeting of the subscribers of the Naval Medical Compassionate Fund will be held on April 19th, at 3 p.m., at the Medical Department of the Navy, Admiralty, S.W.1, to elect six directors of the Fund.

DEATHS IN THE SERVICES

Colonel Robert Bradley Roe, Madras Medical Service (ret.), died at Ipsden, Oxon, on March 5th, aged 75. He was born on March 22nd, 1858, the son of the Rev. Robert Bradley Roe of Wincanton, Somerset, and was educated at St. George's, taking the M.R.C.S. and L.S.A. in 1881. Entering the I.M.S. as surgeon on October 1st, 1881, he became colonel on April 30th, 1911, and retired on May 15th, 1914. Most of his service was spent in civil employ, as civil surgeon of Akola and Amraoti, in the Berars, and later of Nagpur, in the Central Provinces.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The Road Traffic Bill was introduced by Major Stanley in the House of Commons on March 26th. Its chief purpose is to increase safety on roads. It does not incorporate the proposals made in Lord Moynihan's Road Traffic (Compensation for Accidents) Bill. During the week the House of Commons further debated the Unemployment Bill, and took Scottish Bills.

In the House of Lords, on March 21st, the Indian Pay (Temporary Abatements) Bill was read a second time. On March 22nd the Birmingham United Hospitals Bill was reported with amendments. The Wirral Joint Hospitals Bill was reported without amendments, and its third reading was set down for March 27th. On the same date the Dyestuffs Import Regulation Bill and the Rural Water Supplies Bill were reported. The Solicitors' Bill and the British Hydrocarbon Oils Production Bill were read a third time, and the Petroleum Production Bill was read a first time.

A report by the Attorney-General on the Plymouth Hospitals Amalgamation Bill was presented to the House of Commons on March 23rd.

The Parliamentary Medical Committee has asked Mr. Neville Chamberlain to receive representations about the remuneration of medical practitioners under the National Health Insurance Acts. On March 26th Mr. J. H. Thomas received a joint deputation from the Parliamentary Medical Committee and the Social Hygiene Council. The deputation included Sir Francis Fremantle, Dr. Howitt, Captain Ellistoun, Colonel Buchan, Dr. Drummond Shiels, Sir Basil Blackett, Major Orde Brown, and Mrs. Neville Rolfe. It adduced evidence of undue prevalence of disease in Bechuanaland, and the lack of an adequate medical service. Mr. Thomas promised to inquire into the matter.

On March 14th the Conservative Health and Housing Committee met, with Sir Francis Fremantle in the chair. Sir Leslie Scott, chairman of the Central Association for Mental Welfare, and Miss Evelyn Fox, secretary of the association, presented their view of the necessity for a Bill legalizing voluntary sterilization. The committee heard, with sympathy, that the Central Association was rousing support for the Bill on this subject, but during the discussion a general suggestion was made that the subject should be dealt with by a Government Bill.

Methylated Spirit Drinking

The second reading of the Methylated Spirits Bill was moved in the House of Commons on March 23rd by Miss HORSBROUGH. She said the regulations now in force for controlling the sale of mineralized methylated spirit had been applied very fairly, but in some cases carelessly. The present regulations were under the Spirit Act of 1880, amended by the Revenue Act of 1886, and there were certain regulations in Methylated Spirits Orders. One section of the 1880 Act made it an offence to prepare or attempt to prepare any methylated spirit for use as or for a beverage, or as a mixture with the beverage. Another section of the same Act made it an offence to sell any methylated spirit, whether so prepared or not, for a beverage or mixed with a beverage. These restrictions not having proved sufficient, and the number of convictions for drinking methylated spirit having increased, a new formula was introduced in 1924, which included a certain amount of pyridine. For the year after there was a fall in convictions because people believed that what had been added was poison, but since that time there had been a steady increase. The evil of methylated spirit drinking was widespread, and not confined to the poor districts of big towns. In Scotland the figures were higher than in England, and although there had been a sustained decrease in general convictions for drunkenness, convictions for drunkenness due to methylated spirit had not decreased

to any extent. She regretted that the figures were not tabulated in Scotland so clearly as in England, but in six of the largest boroughs the total annual convictions for this offence remained at about 1,000. She had heard of one person being brought before the court fifty-one times, but out of 553 persons apprehended in Glasgow last year 337 were before the court for the first time. In Inverness forty-two out of seventy-four cases of drunkenness in one year were due to drinking methylated spirit, and twenty-three of these were before the court for the first time in 1932. Methylated spirit 60 above proof was sold for 8d. a quart; when mixed with water it was not obnoxious, and it was flavoured with peppermint or with ground ginger. There were many ways of treating the spirit so that the pyridine could be removed. In this Bill no restriction was proposed on surgical spirit or spirit of perfume. When pyridine was added in 1924 permission was given for industrial spirit to be used for surgical purposes under a certain formula. Although castor oil and other ingredients were added to surgical spirit it was still a favourite drink in many places. If a little milk was added and the mixture shaken the castor oil and other ingredients came to the top with the cream, and consumable alcohol was secured. The formula for that surgical spirit had been withdrawn in the previous week by the Customs and Excise, and new formulae substituted from March 15th. She hoped that if the spirit could still be treated so as to make it drinkable the permit for surgical spirit would be removed. To discover whether the drinking of methylated spirit was a danger to the health of the people she had communicated with medical officers of health, police surgeons, professors, and hospital doctors, and none had suggested that it was not injurious. Professor Sydney Smith, professor of medicine at Edinburgh University, said:

"It is much more toxic than ordinary alcohol owing to the fact that it takes much longer to be destroyed in the tissues, and the effect of one dose may last for several days. One of the most disastrous effects is connected with disorders of vision. In the last year or two there have been treated in the Edinburgh Royal Infirmary about thirty cases of definite methylated spirit poisoning, and two of these cases proved fatal. Coupled with toxic poisoning is the poisonous effect on the central nervous system."

The present Bill was based upon an Act in force in Northern Ireland in which the restrictions were perhaps more stringent; that Act had been successful. The Bill suggested that licences should not be granted to a retailer of mineralized methylated spirit unless that retailer had a certificate from the local authority to say that he had been listed as a person who was suitable for the sale and whose premises were suitable. It also provided that the seller's name should be entered in the local authority's list, that the bottle or other container of the spirit should be labelled, that the seller before handing over the spirit to a purchaser should enter in a register the purpose for which the spirit was required, and that the register should be signed by the purchaser. The Bill also provided that a signed order might be taken. If the Bill became law many persons would be warned of the harm due to drinking this spirit. Chief constables in England and Scotland had told her that the effect of putting the onus on the purchaser in the way suggested would check the evil. In many cases the police knew the people who at present obtained this spirit in order to supply it to others, but they had no power to deal with them. Mr. HERBERT WILLIAMS seconded the motion. He suggested that it might be possible to introduce an emetic without destroying the value of the spirit for the purposes for which it was legally obtained.

Sir WILFRID SUGDEN moved the rejection of the Bill. He said that methylated spirit was essential in the medical and dental professions, and in the boudoir. It was used in beauty parlours, and was essential in the engineering trades. He criticized the Bill in detail. Colonel APPLIN, seconding the amendment, said that in country districts methylated spirit was hawked by the oilman's cart, which went round selling groceries and other things, or it was sold in small shops out of a can. The suggested precautions would greatly inconvenience villagers.

Mr. DOUGLAS HACKING, for the Home Office, said that in the opinion of the Government chemist the addition of other liquids to methylated spirit would not get rid of the pyridine. Dilution with water might cause some mineral naphtha to float to the top, but the liquid would still retain a large

measure of the wood naphtha, pyridine, and dye, and would remain nauseous. In England and Wales the problem of methylated spirit drinking was not large. In 1932 convictions for drunkenness so caused were 596, or 2 per cent. of all the convictions for drunkenness that year. This meant that one person was convicted for methylated spirit drunkenness in every 68,000 of the population, or, making an allowance for addicts, not more than one in every 75,000 of the population of England and Wales. The Royal Commission on Licensing had commended to the authorities concerned the desirability of discovering a denaturant which would be even more effective, but the Commission inclined to doubt whether much more could be done by legislative or administrative action to check the drinking of these spirits. He doubted the effectiveness of the provisions of the Bill. He regretted that, so far as England and Wales were concerned, the Government could only leave the Bill to the House. Mr. Hacking also regretted that the Secretary for Scotland had been called away on urgent business, and could not express an opinion on behalf of the Scottish Office. Sir E. GRAHAM-LITTLE said he could not confirm Miss Horsburgh's belief that there was a strong medical opinion in favour of the Bill. The subject had not appeared in the medical press for the last ten years. The medical profession was more concerned with other poisons. Mr. MACQUISTEN said the drinking of methylated spirit was an especial evil in large towns, and the Bill would abate it considerably. The Bill gave local authorities the same power to refuse licences as did the Poisons Act. Mr. BURNETT and Mr. Dingle Foot supported the Bill as representatives of Aberdeen and Dundee. Mr. BURNETT said that of 250 convictions during 1933 for drunkenness in Aberdeen eighty-eight were in respect of the drinking of ordinary alcohol, 124 in respect of red wine often mixed with methylated spirit, and thirty-eight in respect of methylated spirit unmixed.

On the motion that the House divide on the Bill the voting was 48 to 28, and as the numbers were not sufficient to carry the closure there was no division on the second reading.

Road Accidents: Early Legislation

Colonel HEADLAM told Mr. Austrother-Gray, on March 15th, that the Minister of Transport hoped to introduce before Easter a Bill with a view to reducing road accidents. On the same date he told Mr. Leckie that the Road and Rail Traffic Act, which had just come into operation, amended the provisions of the Road Traffic Act of 1930 in regard to payments to hospitals for treating persons injured by motor accidents on the highways. It would be premature to consider further amending legislation now. [Mr. Leckie, in his question, suggested a short Bill compelling insurance companies which covered third-party risks to pay adequate remuneration to the hospitals for their services in these cases.]

Colonel HEADLAM states that arrangements have been made with the Home Secretary and the Secretary of State for Scotland for the number of persons killed and injured on the roads to be reported weekly for a period beginning at Easter, so that they might be available for publication in the coming campaign for the reduction of road accidents.

Vaccination

Replying to Mr. Groves, on March 15th, Sir HILTON YOUNG said he was aware that in Leicester, during the past twenty-five years, not more than 5 per cent. of the children born had been vaccinated; that during the twenty-five years 1905 to 1929 no death was registered from small-pox; that during seventeen of those years no cases occurred; and that during the years 1929 to 1931 two outbreaks of mild small-pox which occurred in the city were attended by only two deaths. These figures might with advantage be supplemented by the Registrar-General's official record that during the 1929-31 outbreak 2,871 cases of small-pox occurred in Leicester (867 of these cases being notified to the local authority in the first quarter of 1931). The facts were well known to his Department and their significance duly appreciated. He saw no reason for instituting a special inquiry.

On March 15th Lord STANLEY told Mr. Groves that in 1933 there were seventy-four cases of catarrh on H.M.S. *Furness*. No case of spotted fever occurred that year, but there was one case in January, 1934. The rating affected

was landed at the Isolation Hospital, Gibraltar. Lord Stanley could not say whether he had been vaccinated or inoculated. Unless they objected on conscientious grounds all officers and men were revaccinated at intervals of five years. They were also inoculated against the typhoid group before a ship went abroad and at intervals during foreign service. It was not the custom to inoculate against spotted fever.

On March 19th Mr. DUFF COOPER told Mr. Groves that no record was kept by the War Office of the number of "bad arms" resulting from the vaccination of recruits, with the exception of cases which were admitted to hospital.

Sir HILTON YOUNG, replying to Mr. Groves on March 19th, stated that it was not with the approval of his Department that registrars of births, marriages, and deaths handed to persons registering births printed matter other than the certificate of registration and Form A under the Vaccination Acts. He was not aware of any statutory authority under which public health committees could require registrars of births to distribute any forms other than those which they were required to issue under the Registration and Vaccination Acts.

Nitrophenol

Replying to Mr. McEntee on March 22nd, Sir JOHN GILMOUR stated he had received a report of an inquest at Paddington concerning the death of a girl from an overdose of a drug of the nitrophenol class. The Poisons Board, set up to advise him under the Pharmacy and Poisons Act of last year, was considering restrictions to be applied to this and other poisons. Meanwhile it was clearly desirable that this drug should be placed under the utmost restriction. He was in consultation with the Lord President of the Council and with the Pharmaceutical Society, who, until the new Act was brought into force, were the responsible authorities, with a view to its being scheduled as a poison at the earliest possible date. He also proposed to take up the matter with the manufacturers, with a view to the adoption of further precautions. He agreed with Sir Reginald Banks that the coroner had said the manufacturers had taken ample precautions against the misuse of the drug by warning on the bottle and otherwise, and that nobody was to blame except the unfortunate woman who disregarded the instructions.

Birth on the Isle of Scarp

On March 20th Mr. T. B. W. RAMSAY asked the Secretary of State for Scotland if he was aware that the wife of James McLennan, Isle of Scarp, who was delivered of a baby by an untrained midwife at Scarp on January 13th, was conveyed over the island, the sea, and the uncompleted Hushinish road on a stretcher to a motor car for transport to Tarbert, Harris, eighteen miles away, on January 14th; that ultimately she was conveyed by car to Lewis Hospital, Stornoway, where she was delivered of a second baby on January 15th; and, seeing that the people of Scarp had repeatedly asked for a trained nurse, pier, and road transport facilities, what action he proposed to take in the matter. Mr. SKELTON said he understood that the facts of the case were generally as stated. Some time before the birth the doctor visited Mrs. McLennan and strongly urged her to go to Tarbert for her confinement. He again saw her a few days before the birth, and repeated this advice. Neither the doctor nor the trained nurse was summoned until after the first child was born. Within two hours of receiving the telephone message asking for assistance they reached the island, and under the doctor's personal supervision the patient was removed to the hospital, where she was successfully delivered of the second child. A doctor and nurse were available in Tarbert, and the installation of a telephone between Tarbert and Hushinish had reduced the difficulty of summoning them to Scarp. The Department of Health was satisfied that these arrangements were adequate. The provision of improved transport facilities was a matter in the first instance for the County Council of Inverness. Mr. RAMSAY asked if Mr. Skelton was aware that the doctor who gave the information mentioned in the question also stated that if a district nurse was given to Scarp the island would be lucky indeed compared with other islands. Mr. SKELTON said he thought if other women in similar circumstances would take the advice proffered to Mrs. McLennan, and go to a proper home in time, many of the difficulties incidental to life on scattered islands would be removed.

Diphtheria Immunization in Acton Schools.—Sir HILTON Young told Mr. Groves, on March 20th, that diphtheria immunization had been carried out by the Acton Town Council in its schools in its capacity of health authority. All children over 7 years of age were Schick-tested before immunization, but the children in the infants' department of one school only were so tested. The immunizing material used was almost wholly T.A.M. (toxoid-antitoxin mixture), but T.A.F. (toxoid-antitoxin floccules) was used in a few cases. Three injections were given in the great majority of cases. The inoculated children were Schick-tested more than three months after the final inoculation. Eight out of approximately 1,600 were still Schick-positive.

Cheap Milk Supply to Hospitals.—Replying to Sir Alfred Beit, on March 15th, Dr. ELLIOT said it would be for the Milk Marketing Board to frame proposals for expenditure from the milk publicity fund. The approved programme was required to contain, *inter alia*, provision for the supply of milk to schools at reduced rates. It would be open to the boards to consider other suggestions, such as that the cheap milk should be supplied to hospitals. On the same date Mr. Elliot estimated the home production of milk in England and Wales during 1933 at 1,368 million gallons; in Scotland at 171 million gallons; and in Northern Ireland at 90 million gallons. Imports of condensed milk during the year were equivalent to 100 million gallons.

Payment of Public Vaccinators.—Sir HILTON Young told Mr. Groves, on March 14th, that he would bear in mind his suggestion that the fee system of payment for services rendered by public vaccination officers should be abolished when he was next promoting legislation or issuing orders dealing with vaccination.

Diphtheria Antitoxin.—Sir HILTON Young told Mr. Groves, on March 15th, that toxoid-antitoxin was still used for diphtheria immunization in this country. There had been no alteration in the strength of the mixtures used during the last twelve months.

Obituary

WILLIAM PRINGLE MORGAN, M.B., D.P.H.
Past President, Sussex Branch

It is with great regret we have to record the death, at the age of 72, of Dr. William Pringle Morgan, in a nursing home in London, from septic endocarditis. Dr. Morgan was born at Rostrevor, Ireland, and received his education at Dundalk Grammar School, Ennis College, and Trinity College, Dublin, where he graduated B.A., M.B., B.Ch. He settled in practice in 1886 at Seaford, which he saw rise from a small fishing village to a good-sized town, with twenty-five schools at the date of his retirement in 1928. Although over age he joined the Army during the Great War, being posted to Malta and Salonika. Among his other activities were the following. He was a member, later chairman, of the Seaford Urban District Council, and chairman of the local branch of the League of Nations Union, and was well known in Masonic circles. He was the third Master of the Seaford Lodge on two occasions. In 1911 he was Provincial Junior Grand Deacon. He was well known for his work in the British Medical Association, especially in Sussex. He was president of the Sussex Branch in 1925, and had acted as one of the Representatives of the Brighton Division—1930-3. He had been elected again by his colleagues for the forthcoming Bournemouth Meeting. All those who met him at the various Representative Meetings will remember that, though he spoke seldom, when he did his utterances, quietly and clearly delivered, were full of sound common sense. When he visited Dublin last year he was full of joy and enthusiasm at once again returning to his Alma Mater, and paid visits to many of his old haunts. His kind and genial hospitality, when president of the Branch, will be remembered by all those who came in contact with him. He was cremated at Golders Green, and on March

24th a memorial service was held at Seaford Parish Church, which was attended by large numbers of old friends, patients, colleagues, and officials, who desired to pay a last tribute of respect to a beloved doctor. He was a man of transparent honesty, always ready to do a kindness when the chance offered. No better tribute can be paid to him than that of his colleagues—"A perfect gentleman." Dr. Morgan leaves a widow, two daughters, and two sons—Dr. A. G. Morgan of Harley Street and Major Morgan of Exeter.

THE LATE DR. DARLEY HARTLEY

Dr. Alfred Cox writes:

Your notice of the death of my old friend William Darley Hartley demands from me a word in recognition of all I owed him, officially and personally, when I was medical secretary. The Empire-wide organization of the B.M.A. lends very often to requests at headquarters for information which can only be satisfied if one has access to reliable sources on the spot. A query about prospects in Canada meant a reference to Routley; about Australia, the never-forgotten Todd; and Darley Hartley was for many years my infallible guide and friend in South Africa. His knowledge of medical affairs in that country and his influence were equalled by his sagacity and kindness. Officially, he combined the offices of editor of the *South African Medical Journal* with a medical agency in which he was assisted by his son, but unofficially he was also the medical secretary for that country, and I always advised doctors who were thinking of settling in South Africa to see Hartley as soon as they could after arrival.

He was an ardent South African, but he firmly believed that it was for the good of that country that its medical profession should be guided by the traditions and ethics of the old country, and therefore he threw himself into the work of organizing the B.M.A. in South Africa with great vigour. My mission to South Africa in 1926-7 was a very difficult one. It would have been an impossible one had it not been for two men who stand out, amongst others, in my memory—Darley Hartley and Orenstein. The morning after my arrival at Capetown I spent with Hartley in his office, and I was, to my great benefit, in close touch with him throughout my tour. Ever since my return I have kept up an occasional correspondence with him, and to the very last he exhibited all those gifts of sympathy and knowledge which endeared him to all who knew him. I am glad to be able to pay this last tribute to a man who richly deserved the honour of being the first Gold Medallist of the Association in South Africa, and the gratitude of all who had the pleasure of working with him.

THE LATE DR. A. G. BARRS

Dr. M. P. K. MEXON (Edmonton) writes:

I would like to add my tribute—the tribute of an Indian student—to the memory of that large-hearted Englishman, the late Dr. A. G. Barrs of Leeds. It was my good fortune to be his clinical clerk at the Leeds Infirmary during my student days—and how I enjoyed those six months! I was thrilled by his personality and overcome by his kindness and his accessibility. He was by no means a textbook teacher. He had no time for rare diseases or miraculous cures. He made one observe the main and essential landmarks of our science, and although at times he may have been a little too sure about his aphorisms we students accepted them, as we loved and respected him. He had great psychological insight into human nature, and always knew, as if by instinct, what his patients and his students desired—and did his utmost to provide it. He was very human, and knew the human failings. The world is indeed poorer for his passing.

The death took place in London, on March 13th, of Dr. ARCHIBALD STODART-WALKER of Denham, Bucks. He was born in 1870 at St. Fort, Fife, and was a nephew of Professor John Stuart Blackie, the celebrated professor of Greek at Edinburgh University. Dr. Stodart-Walker

was educated at Liverpool College and at the University of Edinburgh, where he graduated M.B., C.M. in 1891. He studied also in London, Paris, and Bologna. After acting as resident house-physician to the late Professor Grainger Stewart in the Royal Infirmary, Edinburgh, he subsequently became assistant professor in physiology and clinical tutor at Edinburgh University. He joined the Royal College of Physicians of Edinburgh as a Member in 1895, proceeding to the Fellowship in 1897. After considerable research in the subjects of psychology and neurology Dr. Stodart-Walker abandoned the profession of medicine for that of literature in the year 1898. During his medical course at Edinburgh University he took an active interest in student affairs, being president of the Students' Representative Council in 1890 and president of the Students' Union in 1891; he also acted for a time as editor of *The Student*. He served in the R.A.M.C. during the war with the rank of major, being mentioned in dispatches and receiving the M.B.E. for his services. From 1919 to 1925 he acted as president of the Joint Survey Board at the Ministry of Pensions. Dr. Stodart-Walker published many works dealing with literary subjects, including *The Letters of John Stuart Blackie* in 1909; *The Struggle for Success*, 1900; *Habit and Control*, 1901; *Robert Buchanan, the Poet of Modern Revolt*, 1901; *A Volunteer Haversack*, 1902; *A Beggar's Wallet*, 1905; and *Occasional Verse*, 1920. He was a keen art critic, and founded in 1907 the Scottish Modern Arts Association, of which he was appointed chairman.

Medical News

The British Orthopaedic Association, under the presidency of Mr. Harry Platt, will hold a spring meeting in Holland on Thursday, Friday, and Saturday, April 12th, 13th, and 14th. An interesting scientific and social programme has been arranged. Thursday will be spent with Dr. Murk Jansen at the Anna-Kliniek. On Friday the members will visit the clinic of Dr. Schoemaker at The Hague, and on Saturday the clinic of Professor Noordenbos at Amsterdam. The excursions for members and their ladies will include, amongst others, a visit to the Frans Hals Museum and a special trip to the Bulb Fields.

At the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W., on Tuesday, May 8th, at 5.30 p.m., Dr. Jane Walker, C.H., will deliver a Chadwick Public Lecture on "Village Hygiene; Water Supply; Disposal of Refuse." Sir James Crichton-Browne, F.R.S., will preside. Admission free, without ticket.

The Royal Sanitary Institute has arranged a sessional meeting at the Town Hall, Bolton, on Friday, April 13th, at 5 p.m., when a discussion on "Public Baths in Relation to Health and Disease" will be opened by Dr. R. M. Galloway, medical officer of health, Bolton; to be followed by a discussion, opened by Mr. Cyril H. Walker, on "The Technique of Rehousing, etc., from Slum Areas."

A three months' course in clinical practice and hospital administration will be given at the Brook Hospital, Shooter's Hill, S.E., by Dr. J. V. Armstrong, on Mondays and Wednesdays, at 9.30 a.m., and alternate Saturdays, at a time to be arranged, beginning April 4th. It is intended for those studying for the D.P.H., and complies with the requirements of the General Medical Council's revised regulations, which came into force on October 1st, 1931. A course may, however, be taken under the previous regulations for £4 4s. The fee (£3 13s. 6d.) should be paid to the medical officer of health, L.C.C. Public Health Department (Special Hospitals), County Hall, S.E.1.

The Fellowship of Medicine announces a further lecture-demonstration, on shortness of breath, by Dr. Clark-Kennedy, at 11, Chandos Street, on April 10th, at 2.30 p.m. (There will be no lecture on April 3rd.) An all-day course in proctology will be given at St. Mark's Hospital from April 9th to 14th. There will be an afternoon course at the Infants Hospital from April 9th to 21st; and an evening course in rheumatism at the British

Red Cross Clinic, Peto Place, on Tuesdays and Thursdays, from April 10th to 26th. A week-end course in general medicine and surgery has been arranged at the Southend-on-Sea General Hospital on April 14th and 15th. Six lectures on the diagnosis and treatment of chronic diseases of the chest in general practice will be given by Dr. Ellman, at 11, Chandos Street, on Wednesdays and Fridays, at 8.30 p.m., from April 11th to 27th. Demonstrations for candidates for the M.R.C.P. have been arranged during April, and particulars may be had from the secretary of the Fellowship, 1, Wimpole Street, W.1. Other forthcoming courses include ophthalmology at the Royal Eye Hospital, April 16th to 28th; gynaecology at the Samaritan Hospital, April 28th and 29th; psychological medicine at the Maudsley Hospital, April 30th to May 26th; dermatology at St. John's Hospital, April 30th to May 26th. Three lectures (free to members and associates of the Fellowship) will be given at the Medical Society of London, on April 19th, 26th, and May 3rd; the first, by Mr. F. W. Edridge-Green, will deal with vision and colour-vision.

In connexion with the inauguration of the new State-built thermal establishment at Aix-les-Bains an international scientific conference on rheumatoid arthritis will be held in that town from June 28th to July 1st, under the patronage of the French League against Rheumatism. The chairman will be Professor Bezançon of Paris, and discussions will be opened by Sir William Wilcox and Drs. S. Gilbert Scott and F. J. Bach, among others. Inquiries should be addressed to M. Dussuel, Rue du Casino 1, Aix-les-Bains (Savoie), France.

The fifth Congress of Yugoslav Surgery will be held at Belgrade from April 28th to May 1st, when the following subjects will be discussed: surgical tuberculosis of the lungs and pleura, introduced by Professor Kostitch of Belgrade; fractures of the long bones of the extremities, introduced by Dr. Florschütz of Zagreb and Dr. Simovitch of Belgrade; and indications for the Caesarean operation, introduced by Professors Durst of Zagreb and Bogdanovitch of Belgrade.

The French Society of Ophthalmology will hold its forty-seventh congress in Paris from May 14th to 17th, when the chief subject for discussion will be biomicroscopy of the normal and diseased conjunctiva, introduced by M.M. Cuenod and Natal of Tunis. Further information can be obtained from the general secretary, Dr. René Onfray, 6, Avenue de la Motte-Picquet, Paris, 8e.

The Oxford University Press has ready for early publication, as an addition to the Oxford Medical Publications, *The Menace and Geography of Eclampsia in England and Wales*, by Dr. Norman Porritt.

The King has confirmed the appointment of Dr. J. O. Shircore, C.M.G., to be an unofficial member of the Legislative Council of the Tanganyika Territory.

On March 21st the Mayor of Torquay reopened the Corporation warm sea-water swimming bath, which has been entirely refitted on modern lines, and is now equipped with a Bells filtration plant, with a three-hour turnover which chlorinates, aerates, and warms the water as it passes through the filters. The ceremony was attended by representatives of the local medical profession.

On March 23rd a special service was held in Carlisle Cathedral to celebrate the centenary of the death of Dr. John Heysham, founder of the Carlisle Dispensary, and author of the *Carlisle Tables of Mortality*. Some account of the proceedings, and of Dr. C. W. Graham's commemorative oration, will appear in a later issue.

According to statistics issued by the League of Nations, the population of the world amounts to 2,012,800,000, to which Asia contributes 1,103,000,000, Europe 506,000,000, North America 252,000,000, South America 83,000,000, Central America 34,000,000, Africa 142,000,000, and Oceania 10,000,000. These figures represent an increase of 20,000,000 over those of 1930.

The Prussian Home Office has recently drawn the attention of mothers, midwives, and clergymen at baptism to the increased prevalence of pemphigus neonatorum.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:
EDITOR OF THE BRITISH MEDICAL JOURNAL, *Atiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dubhu*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshigh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Bacte-rhino-phage In Asthma

"M.D." (Devon) would be glad to hear from anyone who has had experience of bacterio-rhino-phage in the treatment of asthma. He also asks for references to English literature thereon.

Use of Quinine In Normal Labour

Dr. W. J. BURNS SELKIRK (Birmingham) writes: May there not have been an old fallacy in Dr. Sheinkin's (March 17th, p. 516) argument—namely, that the tablets passed through undissolved? It has seemed to me that the preliminary quinine (given in solution) helps one to choose a suitable day of confinement about full term, the hot bath and castor oil being more successful following the period of medication by quinine.

"G. B." writes: If Dr. Sheinkin had given doses of 1/2 to 1 grain three times a day, and limited his time to the last six or eight weeks, his results might have been better.

The Pox Doctor's Clerk

Dr. GEORGE JONES (London, S.E.) writes with reference to Dr. Philip Gosse's inquiry about "the pox doctor's clerk": Forty years ago the late Dr. Jukes de Styrap was a frequent contributor to your columns, chiefly on medical ethics. He published in 1890 a small book called *The Young Practitioner: His Code and Tariff*. At page 85 he wrote: "Be careful that your repute for special interest in venereal diseases does not obscure and surpass that for other maladies, otherwise you may get the unenviable title of 'P-x Doctor,' and entail social ostracism and the loss of family practice. . . . by perpetually inquiring about the urine, and having it kept and bottled for you, earn the easily acquired title of 'P-s Doctor.'" That our forefathers were in the habit of using plain words is known to every reader of Shakespeare: 2 *Henry IV*, Act I, Sc. ii, line 258 and below. "The gout galls the one, and the pox pinches the other. . . . A pox of this gout! or, a gout of this pox! for the one, or the other, plays the rogue with my great toe."

LETTERS, NOTES, ETC.

History of Nitrous Oxide Anaesthesia

Dr. F. WILLIAM COCK, F.S.A. (Appledore, Kent), writes: In 1887 my old fellow-student, Dr. Dudley Buxton the anaesthetist, introduced me to J. F. Blennerhasset, who fitted me out with anaesthetic apparatus for a good many years. The N₂O bottles were of steel, with the flat bottoms welded in. "J. F. B." was a quaint bird, clever, ingenious, and perfervid, even to making interruptions at the local vestry or similar meetings: long-haired, with much-tangled beard, and with a very likeable chap. After he died, or gave up, I was supplied by Barth and Co. for many years. Somewhere in the early 'nineties I attended an old gentleman named Orchard, who claimed to be the first to

condense oxygen in a cylinder. A man was killed at Fenchurch Street Station by the explosion of a gas-filled cylinder. The old gentleman, contrary to my orders, would attend the inquest to find out where the fault in the metal was. It was winter, he increased his bronchitis, took to his bed, and though I believe I kept him alive for at least a week by the use of his own oxygen (warmed by passing through a coil of gas-metal tubing placed in a pail of hot water), he ultimately died "drowned in his own secretions." The early cylinders were a great nuisance by reason of the freezing of the water vapour in the neck. I believe I shared the idea of putting a turned-up tube inside the delivery tube of the bottle, thus preventing the liquid gas escaping into the neck, freezing itself and the water vapour. But that is a long time ago.

Chilblains

"A. S." writes: Dr. Gillison's letter on chilblains recalls my meeting a patient in a tram last autumn. Besides the weather, she complained of chilblains. As I have great faith in this, I said, "It is four years since I wore gloves, and I since then I have never had a chilblain." She smiled and said, "But mine are on the toes." I jokingly said, "In that case you will have to wear nothing but sandals." Her reply, "I know what you mean, but it might have been better expressed," made the next car-stop a convenient alighting place. I suppose Dr. Gillison would advise the elastic bands round the ankles whilst dressing, and then to lie on the bed with the legs as high as possible—an exercise that would at least tend to improve one's appetite for breakfast.

Adjustable Thermostat for a Car

Dr. MAXWELL K. BARNETT (Southampton) writes: I should like to call the attention of other general practitioners to the great benefits of an adjustable thermostat on a car. After running seven cars (two of which had radiator shutters) I have come to the conclusion that this is the ideal control for any machine which is left out for long periods in the cold and seldom properly "warmed up." On my "A.C." the temperature of the water in the cylinder block rises to 70° in two or three hundred yards' running, and I never have difficulty in starting from cold. The thermostat can be adjusted (if necessary) in a few seconds, and without soiling one's hands. I need hardly mention that I have no financial interest in this fitment.

CO₂ Therapy In Lobar Pneumonia

Surgeon Lieutenant A. F. DAVY, R.N., writes: I read with interest Dr. Hilton's article on the above subject in the *Journal* of March 10th (p. 418), and in particular the conclusions he had drawn. Surely, if pneumonia is an acute general infection with a local manifestation in one or both lungs, one's aim should be to rest the lungs as much as possible to avoid any further spread of infection. In these circumstances would not CO₂ be definitely contraindicated, except in very special circumstances?

Professor Adolphe Pinard

The death of Professor Pinard (writes our Paris correspondent) has been the signal for a remarkable demonstration of affection and regret, not only in the medical, but also in the lay Press. In the French Academy of Medicine also he was the subject of a glowing tribute by its president. No epoch-making discoveries are associated with his name, and for this reason history will perhaps forget him. But he did very useful work by applying the discoveries of others, from Pasteur's onwards, to the problems of daily life as they affect mother and child. With his aptitude for thoroughness he spent the first half of his life drilling into all with whom he came in contact—medical students, nurses, midwives, and others—the essentials of clinical obstetrics. At the Baudelocque he was the centre of the younger generation of medical men, foreigners as well as Frenchmen. At the Academy of Medicine, to which he was elected in 1892, at the Conseil Supérieur de la Natalité, in the Chamber of Deputies, and wherever else he could make himself heard, he was the untiring advocate of reforms. The latter part of his life was spent in infant welfare work, and he took a leading part in the education of nurses. When his health began to fail, about a year ago, he retired to the country in the neighbourhood of his birthplace, and he passed away about four weeks after celebrating his ninetieth birthday.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 34, 35, 36, and 37 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 38 and 39. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 132.

TREATMENT OF GONORRHOEA IN WOMEN BY MERCUROCHROME, WITH SPECIAL REFERENCE TO COMPLICATIONS

A FURTHER REPORT

BY

R. S. STATHAM, M.D., CH.M., F.C.O.G.

PROFESSOR OF OBSTETRICS, UNIVERSITY OF BRISTOL; HONORARY GYNAECOLOGIST, BRISTOL ROYAL INFIRMARY;
MEDICAL OFFICER TO BRISTOL VENEREAL DISEASE CLINIC

About six years ago I contributed a short paper to the *British Medical Journal*,¹ describing a method of treating gonorrhoea in women by swabbing with 1 per cent. mercurochrome solution. This paper was based upon a short experience and a limited number of cases, but it showed such good results that I was encouraged to continue the same treatment on a larger series of patients, and over a time sufficiently long to enable recurrence to be detected, even if it occurred after a considerable interval.

The present paper embodies the experiences of the last five years. During this time about 450 cases of proved gonorrhoea have been treated with this method by myself and my colleagues, and I have been in no way disappointed with the results. The patients have attended well, and have expressed their appreciation of the slight inconvenience caused by this technique. The recovery rate has been satisfactory, and the recurrences have been few, but so many variables occur in cases treated by different members of the staff of a clinic that I have thought it well to reduce the cases for this paper to 158. These 158 have all been treated by myself. They have all attended until finally discharged as "cured" after full tests. They have all been treated by the mercurochrome method only, so that I think they can be used as the basis of statistics to form a fair estimate as to the value of mercurochrome in the treatment of gonorrhoea when used in this way.

METHOD OF TREATMENT

This was fully described in my previous communication.¹ Briefly, it consists in applying 1 per cent. mercurochrome to the cervix and vagina, with the latter fully stretched out by a fenestrated speculum. The application is preceded by a warm douche of saline, accompanied by swabbing to get rid of pus and mucus. This is repeated daily. No advantage has been found in using the mercurochrome in stronger solution than 1 per cent., and there is some evidence to show that when stronger than 2 per cent. it tends to the formation of "erosions." In cases complicated by urethritis and cystitis the bladder also is irrigated.

CRITERIA OF CURE

In this series the criteria of cure are essentially the same as in the previous group. The main tests are: three consecutive sets of smears from cervix and urethra, taken at a month's interval after the usual menstrual period; also a negative culture from the same regions, and a negative complement-deviation test for gonorrhoea. All these tests are taken after treatment has ceased. A "final test" in which smears, cultures, and a complement-deviation test are repeated is performed three months later. The reliability of this method is shown by the very low incidence of recurrence, and the fact that a number of these cases were attending my gynaecological out-patient department at varying intervals after treatment, yet none has ever given a positive result since treatment was stopped, though frequently tested. It is surprising that it should still be so very necessary to

stress the importance of stopping douching as early as possible in cases of cervicitis. The presence of an "erosion" will cause a mild discharge, which is aggravated as long as hot douching is in use. Frequently cases, which originated as gonorrhoea, are treated for many weeks, and even months, longer than is necessary because it has not been recognized that the discharge is due to the erosion and cervicitis, and not to an active gonococcal infection. Stopping the douche, and application of the cautery, will effect a cure in a few days in most of these cases.

RESULTS AND COMPLICATIONS

This paper has been compiled with a special view to ascertaining whether the mercurochrome swabbing method was, or was not, effective in preventing complications, and most careful watch was kept upon all the 158 cases from this point of view.

TABLE I.—Total Number of Cases under Review, 158

Associated with syphilis	...	13 = 8.2 per cent.
Associated with pregnancy	...	15 = 9.5 "
Became pregnant during treatment...	2 = 1.2 "	

No mother or child developed any unusual symptoms. No case of ophthalmia was recorded. One mother was delivered by Caesarean section on account of pelvic contraction.

TABLE II

Average number of days under treatment until the first negative smear was obtained*	...	37.2
Longest number of days under treatment (1 case)	...	84
Shortest number of days under treatment (2 cases)	...	8

* First negative smear means the first smear of the final series. If a positive appeared later the series was started again and the previous negative smear not counted.

Just over three weeks' treatment—that is, during the interval between one period and the next—was sufficient in the majority of cases to render the next smear negative. It was noticed that the few resistant cases took a long time to clear up, and that there were very few intermediate types of infection.

TABLE III.—Number of Complications

Large erosion of cervix	...	16
Salpingitis	...	14
Bartholinitis	...	6
Acute cystitis	...	3
Rheumatism	...	3
Eye symptoms	...	2

Total (occurring in 35 cases) ... 44

Cases making an uninterrupted recovery, 123 = 77.8 per cent.

In ten cases the only complication noted was an "erosion" of the cervix, and this is so much a part of a cervical infection that it can hardly be considered a complication. If these cases are deducted, the cases making an uninterrupted recovery were 133, or 83.5 per cent.

DETAILS OF COMPLICATIONS

Many of the complications were present when the patient first attended the clinic, as is shown below, and only a few developed during course of treatment.

TABLE IV

	On admission	During treatment
Erosion, persistent ...	11	5
Salpingitis ...	9	5
Bartholinitis ...	5	1
Acute cystitis ...	3	—
Rheumatism ...	2	1
Eye symptoms ...	2	—
	32	12

If the erosions are again disregarded, it will be seen that one case of Bartholinitis, one of rheumatism, and five cases of salpingitis occurred during the treatment of 127 cases, which gives a proportion of 5.5 per cent. complications. This seems satisfactorily low when the mild type of complication is taken into account.

Erosion

Sixteen cases of persistent erosion of the cervix were noted, these being large enough to require definite treatment (small erosions clearing rapidly without special treatment are not counted). The five which developed during treatment were all in cases which took a long time to clear up, and in two of which there was a suspicion of reinfection. In ten cases there was a greater or less degree of cervical laceration and a probability of old-standing cervicitis with chronic infection, as there was a history of "whites" for some years. The treatment was in every case the same. As soon as negative smears had been obtained twice the erosion was cauterized with an electro-cautery. Radiating lines were drawn with the cautery from the cervical canal outwards to the periphery of the cervix and any Naboth's follicles were punctured. This procedure does not cause any pain if gentle pressure and fairly rapid movement are maintained with the cautery. In no case was any anaesthetic needed, and in no case did any patient object or refuse to return to complete the treatment. There is no need to apply a vulsellum, provided an efficient speculum is used. The number of treatments necessary is shown below:

TABLE V

Cauterized on 2 occasions ...	7 cases
" " 3 " ...	5 cases
" " 4 " ...	1 case
" " 5 " ...	2 cases
" " 8 " ...	1 case
	16 cases

In all these cases the down-growing epithelium was completely replaced by smooth squamous epithelium or scar tissue, and the erosion was quite "cured" before discharge. In two cases operation was advised owing to the old laceration, and in one case it was performed six months later, the other patient refusing owing to the symptoms having quite disappeared.

Salpingitis

This complication is known to be very rare in women who have never become pregnant, for the reason that while the internal os remains intact it is almost impervious to any organism. The extensive lymphatic drainage and the facility with which organisms are dealt with have often suggested comparison with the tonsil, but the cervix appears to present a complete bar to the passage of organisms, when it is not interfered with.

The passage of a child, or the products of an abortion, in patients infected with gonorrhoea are followed in many cases by an ascending infection with consequent salpingitis of a more or less severe type. The frequency of the one-child marriage, in a patient with mild or chronic gonococcal infection, is, of course, due to this fact. Any method of treatment entailing passing instruments through the internal os is to be condemned as strongly as possible.

No matter how potent the antiseptic used, some active organisms may be pushed up past the internal os, with consequent ascending infection. A colleague, who was unfortunate enough to be persuaded to try a technique based on passing probes armed with antiseptic swabs up the cervical canal, was horrified to find three cases of acute salpingitis develop in five weeks, all in nulliparous girls, a higher incidence amongst nulliparae than was experienced during the whole preceding five years.

The fourteen cases of salpingitis which are included in this series fall into two groups. Nine women were suffering from infection of the tubes and pelvic peritoneum when first seen; five developed these conditions while actually undergoing treatment.

TABLE VI

Salpingitis Cases Infected Before Admission

1. Mild salpingitis, right and left. Last confinement eight months previous to first visit to clinic. Cleared up rapidly with treatment.
2. Acute salpingitis, right and left. Last confinement sixteen days previously. (Baby with gonorrhoeal ophthalmia.) Cleared up with palliative treatment.
3. Chronic salpingitis, right and left, with swollen tubes. Last confinement eight months previously. Palliative treatment four weeks, then Bartholin's abscess. Gonococcal rheumatism after sixteen weeks' treatment, although she had negative smears and cultures. Did not get really well for twelve months.
4. Right pus-tube. Aborted eight weeks previously. Palliative treatment, and refused operation. Pregnant four months later—aborted with crochet-hook—no ill result.
5. Acute salpingitis, right and left. Last confinement two years previously. Clinical cure with expectant treatment. Normal pregnancy two years later.
6. Very large pelvic mass involving all organs. Did not want operation. Nulliparous—greatly improved by expectant treatment, and remains well except for some dysmenorrhoea.
7. Salpingitis, very acute, right and left. Miscarried eight weeks previously. Good result with expectant treatment.
8. Acute salpingitis, right and left. Expectant treatment for four weeks. Refused operation. Four months later, when apparently "cured," sudden obstruction by adhesions. Operation. Both tubes left in, and in fair condition. One tube patent to fluid. No gonococci found in sinuses from peritoneum, tubes, or cervix.

Salpingitis Developing after Admission to Treatment

1. After three weeks' treatment developed a mild salpingitis. Last pregnancy twenty-six weeks previously. Rapidly got well with palliative treatment. A mild attack of cystitis next developed. She was actually treated for seventy-six days. (Small erosion formed, which was cured by cautery.) Final result good.
2. Acute salpingitis, right and left, ten days after treatment was started. Last pregnancy six months previously. Complete recovery with palliative treatment.
3. Left-sided salpingitis on thirteenth day of treatment. Last pregnancy six months previously (child had "sticky" eyes). Rapidly recovered with palliative treatment. One healthy child since.

Salpingitis Developing after Treatment had Finished

One patient became pregnant eight months after treatment had been stopped, and then aborted after "some instrument" had been passed. She then developed acute pus-tubes, which had to be removed by operation five weeks later. Numerous tests failed to show gonococci in cervix or urethra, or in pus from tubes.

The same method of treatment was adopted in every case. It is hardly necessary to point out the danger of operation in cases of acute salpingitis—unless done at the very earliest stage possible (Bourne²). The work of Hendry³ and his colleagues very completely demonstrates this. Palliative treatment is invariably carried out until the acute symptoms have subsided. Immediate operation may be needed in the extremely rare cases when general peritonitis appears to be definitely threatened.

The method adopted here is quite simple and easy, provided that there is an ample supply of hot water, for heat is the real key to success. The patient is kept well propped up in bed and is given magnesium sulphate in sufficient quantities to obtain two or three watery stools a day; this keeps the pelvic colon empty and prevents the pain and backache so commonly complained of when the full colon presses upon the inflamed contents of the pouch of Douglas. Hot douching is carried out twice a day; the water is used as hot as the patient can bear it, and the douching is continued for at least fifteen minutes. This necessitates a very large supply of hot water, as it is

found that about 2½ to 3 gallons are needed for each patient. When home treatment is carried out in chronic cases, douching under water, in a bath, is convenient and efficient if there is a good supply of hot bath-water available. (This method was described in detail in an article by me in the *British Medical Journal*, 1929, ii, 661.) In almost every case the acute symptoms rapidly subside, the temperature and pulse fall to normal, and the patient experiences great relief. When the symptoms have subsided the patient is examined bimanually to assess the amount of permanent damage, if any. The mercurochrome treatment, which was in abeyance during the acute stage, is restarted, and efforts are made to build up the patient's resistance by fresh air and a liberal diet. In a very few cases the acute condition shows signs of recurring after having subsided for a few days, and then operation is indicated at once if the patient is seen early. If not, the palliative treatment is carried out once more, but laparotomy is performed as soon as the state of temperature and pulse justifies such interference. This treatment is most successful, and from a summary of fifty cases treated in my gynaecological wards during the last three years the following figures appear from a follow-up inquiry:

50 Cases of Acute Pelvic Peritonitis

- 31 "cured"—that is, no complaints and no physical signs.
13 "greatly improved."
6 required operation.

So that only six cases required operation because of recurrence or failure to yield to treatment. Of course, some of these cases will come to operation later on because of chronic dysmenorrhoea and pelvic pain due to adhesions following the old peritonitis, but this lies outside the scope of the present paper, which shows that only two of the cases of salpingitis thus treated at the clinic came to operation, and in one case the cause of operation was intestinal obstruction.

Bartholinitis

Four cases were admitted to the clinic with a Bartholin abscess. Of these, three were treated by operation—that is, incision and swabbing with pure carbolic. Two were apparently cured, and one had the cyst dissected out intact when it appeared again after the first incision. One patient refused operation, and the abscess burst and recurred on three successive occasions before she would consent to excision. A cure was finally attained. The case which developed a Bartholinitis during treatment was cured by excision.

Cystitis

Three cases were admitted with very severe cystitis. In only one case was the gonococcus found in the urine. Twice daily irrigation of the bladder, and the leaving in of 2 oz. of 1 per cent. mercurochrome, rapidly improved the condition, and all signs and symptoms were cleared up after three weeks' treatment at the longest.

Rheumatism

Two cases were admitted with acute gonococcal rheumatism; in one case the right shoulder was severely affected, in the other the swelling began in the right elbow and then attacked the right wrist. Splinting and rest, accompanied by active treatment to vagina and cervix, very soon cleared up the condition. Aspirin in large doses was found to be the best analgesic. The case which developed rheumatism under treatment showed a series of subacute arthritic attacks in different joints. No joint was very severely attacked, but the total time under treatment was nearly six weeks. This case also developed a mild cystitis. In all cases "movements" were started as early as possible.

Eye Symptoms

Two cases developed a mild cyclitis; neither of these had a positive Wassermann reaction. One patient had also gonorrhoeal arthritis, and the other case occurred in a woman who developed salpingitis on the thirteenth day of treatment.

CONCLUSION

Since this paper is based upon cases which have all undergone complete treatment and observation by myself alone, it has been necessary to rule out all those women who did not complete the full treatment, or who were not considered cured. This prevents any statistics being given which show the comparative efficiency of the method. From a rough count of the original 450 cases from which these 158 cases have been drawn, I was able to obtain the following figures, which are only approximately correct.

Total Cases, 450

Clinical Cures, 400.—Many did not complete the final tests and would not return to do so, but had been quite free from symptoms for some weeks.

Ceased to attend, 38.—Most of these had been free from clinical symptoms for several weeks.

Failed to improve, 7.—Four of these were cured by other methods, and three refused to continue here.

Remitted, 5.

Two points at once become evident when these 450 are considered. First, the very small number who "ceased to attend," and this is attributed to the rapid improvement in the patient's condition and to the simplicity and short duration of each daily treatment. Secondly, the high percentage of clinical cures obtained with such a short period of treatment. It is, of course, fully open to anyone to criticize the word "cure" used here, seeing that in many cases the full number of tests had not been carried out, but I think it is a fair inference that the missing final tests would have remained negative in the vast majority of cases, seeing that they did so in almost every one of the 158 cases which were fully observed. I feel, therefore, it can be claimed that treatment with 1 per cent. mercurochrome—provided it is efficiently carried out—is a very rapid and easy method of curing gonorrhoea in women, and is a method which keeps complications at a very low percentage of incidence.

Finally, I think many failures are due either to using the mercurochrome too strong, which injures the power of resistance of the epithelium, or to using a substance which is not genuine mercurochrome. This latter point is of great importance, and needs careful consideration.

I have to thank Dr. Hardy Kingston, the director of the clinic, for his permission to publish this paper, and also the sister and nurses for their great co-operation and help. The obstetric department of the University of Bristol has defrayed the small cost involved.

A national conference on maternity and child welfare will be held in the Town Hall, Birmingham, on July 3rd, 4th, and 5th, preceded by a short clinical course for medical practitioners on July 2nd. The programme has been drawn up on behalf of the National Council for Maternity and Child Welfare and its constituent bodies by the National Association for the Prevention of Infant Mortality, in co-operation with the Maternity and Child Welfare Group of the Society of Medical Officers of Health. Particulars may be obtained from the honorary secretary, Miss J. Halford, Carnegie House, 117, Piccadilly, London, W.1.

EPHEDRINE SULPHATE AND BARIUM CHLORIDE IN THE PREVENTION OF STOKES-ADAMS SEIZURES

BY

A. RAE GILCHRIST, M.D., F.R.C.P.Ed.

ASSISTANT PHYSICIAN, ROYAL INFIRMARY, EDINBURGH

The peculiar syncope attacks which are named after Stokes and Adams have as their predominant feature either a complete and transient cessation of ventricular beating or else the temporary development of such an extremely slow ventricular rate than an adequate cerebral circulation is not maintained. Complete ventricular arrest is the commoner variety. Recovery of the heart beat may take place after a pause of some seconds, or even of five minutes, duration.¹¹ Extreme bradycardia is a less frequent cause of Stokes-Adams seizures. Should the ventricular rate fall to less than nine or ten beats per minute then a semi-conscious stuporose state is apt to arise. This persists until a greater rate of blood flow through the brain is brought about by an increase in the rate or power of the ventricles. On the other hand, a further reduction in rate, perhaps to six or seven beats per minute, is accompanied by loss of consciousness, cyanosis, muscular twitchings, and a deepening coma, which can only be relieved by a more efficient pumping action of the heart.

STOKES-ADAMS ATTACK: PREDISPOSING CONDITIONS

Stokes-Adams seizures develop in a variety of circumstances. In partial heart-block associated with a progressive defect in the conducting power of the bundle of His, seizures are apt to occur over the period when, starved of their full quota of impulses from the sino-auricular node, the ventricles are left to initiate their own independent rhythm. Vagal stimulation in the presence of a pre-existing partial block of toxic origin is a potent cause of ventricular standstill. In such cases I have seen typical Stokes-Adams seizures induced by digitalis, by vaso-eccrotid pressure in the neck, and, in one instance, by sudden over-distension of the rectum during the hasty administration of an enema.

Repeated or single seizures may herald the onset of permanent complete block, and, the idioventricular rhythm becoming firmly established, the patient may live for years, never to experience another Stokes-Adams attack. But seizures at irregular and infrequent intervals, either in the course of chronic partial or in complete block, associated with permanent degenerative changes in the conducting tract, are less easy of explanation. Uncommonly, seizures appear in rapid succession for a number of days, cease of their own accord, only to return again in a few weeks or months for no very obvious reason. One patient under my observation had 352 fully developed Stokes-Adams attacks with loss of consciousness (exclusive of many minor attacks of giddiness and faintness) between April, 1930, and January, 1932. The seizures occurred in groups for a few days at a time: there were as many as 131 attacks over a period of four days. Ventricular fibrillation was demonstrated as the cause of the temporary arrest of the circulation in this patient. In intermittent complete heart-block, in which periods of total failure of the bundle of His alternate from time to time with shorter or longer intervals during which the auricular impulse is carried to the ventricle, repeated seizures of great severity are common, and may progress in spite of treatment to a status epilepticus, with a fatal termination.

That the underlying cardiac mechanism responsible for the temporary arrest of the circulation therefore varies in different cases, and probably also even in the same individual at different times, is a fact more fully appreciated in recent years. It would seem established that in the majority of Stokes-Adams attacks occurring in the course of chronic complete block the centre of impulse formation controlling the ventricular rhythm becomes suddenly depressed, and until it, or another centre, awakens, a critical state exists, during which the circulation is in abeyance. Whether the attack is precipitated by preponderating vagal influences, reduction in sympathetic tone, a block of the idioventricular impulse itself, the development of ventricular fibrillation, or by the presence of unknown chemical factors in the blood stream, is of less consequence than the fact that in complete heart-block the ventricular rhythm is, as a general rule, peculiarly sensitive to sympathetic stimulation.⁶

VALUE AND LIMITATIONS OF ADRENALINE

It has been shown that adrenaline is capable of arousing a dormant ventricular rhythm. When seizures are recurring frequently no drug has proved more effective in their prevention than adrenaline.^{14 17} It is not always successful, but until we have a greater knowledge of the different mechanisms responsible for the Stokes-Adams attack it will not be possible to discriminate accurately between those who will benefit from its use and those who will not. It should always be given a trial when seizures happen frequently. When attacks appear only at long intervals their prevention with adrenaline is less easy. Ineffective by the mouth, and relatively short in its action, adrenaline cannot well be employed for this purpose. Ephedrine and barium chloride, both of which are alleged to increase the rate of spontaneous ventricular beating, have been suggested for use in those cases of block in which seizures occasionally arise at infrequent intervals. Both may be taken orally over long periods of time, and neither produces much systemic disturbance.

THE ACTION OF EPHEDRINE AND BARIUM

It would appear that, while ephedrine in large doses may act as a depressant to the mammalian heart, yet the cardiac stimulant effects of smaller quantities are quite well marked in the case of the human heart.² Its effects in therapeutic doses are less intense than those of adrenaline, but they persist for a longer time. Their similarity in action is indicated by the fact that, while adrenaline stimulates the myoneural junction of the sympathetic system, ephedrine acts upon the nerve endings of the sympathetic fibres.¹ The ventricles receive a rich sympathetic supply; and, though no experimental observations are available regarding the action of ephedrine on the blocked heart of animals, from analogy with the action of adrenaline, and from the few isolated instances in which the drug has been used in clinical examples of heart-block, it is not surprising to find that an acceleration of the ventricular rate was induced. Miller,¹² the first to test the action of ephedrine in complete heart-block, found that in his patient the auricles increased in rate from 110 to 125 and the ventricles from 33 to 55 per minute after a subcutaneous dose of 100 milligrams. Hollingsworth⁹ found that in a case of complete heart-block daily doses of 50 mg. by mouth were sufficient to abolish repeated Stokes-Adams seizures. Within forty-eight hours of withdrawing the drug the attacks recurred. Stecher^{21 22} reported a similar case. Parade and Voit¹³ found thyroxine, caffeine, and digitalis ineffective in preventing seizures, but when taking a synthetic preparation of racemic ephedrine by mouth their patient obtained practically complete relief for a period of two years. The drug was then discontinued,

attacks soon reappeared, and death in a seizure followed before adrenaline could be administered. Wood²² presents very convincing evidence of the value of ephedrine. In his patient 24 mg. twice daily were sufficient to control typical Stokes-Adams seizures over many months. Roberts and Taber¹⁹ found that 25 mg. of ephedrine twice daily controlled attacks in their patient. Death supervened in a seizure twenty-four hours after a further reduction in the daily dose.

As regards the value of barium chloride in the prevention of attacks, the reports in the literature are often at variance, and are decidedly less convincing than the results obtained with ephedrine. The experimental work of Rothberger and Winterberg²⁰ and van Egmond,² which indicated that the excitability of the ventricular muscle was increased by barium chloride, suggested to Levine¹⁰ its clinical application as a possible remedy for the prevention of Stokes-Adams seizures. Colln and Levine,³ in reporting three cases of the Stokes-Adams syndrome, formed a favourable impression of the value of barium chloride; but it is admittedly difficult to distinguish between a spontaneous alleviation of symptoms and a definite effect produced by the drug. Reviewing the work of Levine,¹⁰ Levine and Matton,¹¹ Herrmann and Ashman,⁸ Parsons-Smith,¹² Strauss and Meyer,²³ and Price and Nisse,¹⁶ the conclusion is reached that, in general, barium chloride does appear to have some effect in reducing the frequency of seizures. On the other hand, Wilson and Herrmann²¹ have reported that in a case of complete block, complicated by repeated convulsive syncopal attacks, barium chloride administered in doses of 1/2 grain thrice daily for thirty-eight days was without benefit. Stokes-Adams attacks recurred repeatedly despite its use. The more recent clinical accounts of Drake⁴ and Heard,⁷ and the absolutely negative results obtained by Parsonnett and Hyman¹⁴ in eight cases of complete heart-block, clearly cast a doubt on the efficacy of this drug, and fail to substantiate the more optimistic reports of some years ago.

CLINICAL TESTS

As a means of estimating the worth of these drugs two methods were employed. It seemed desirable to discover if, when they were given by mouth, any significant change took place in the rate of the independent ventricular rhythm. Cases of complete heart-block, free from seizures for months or years, were selected for the test. After an ample control period of ten days or more, during which no drugs were administered, the patient being strictly confined to bed, ephedrine or barium chloride was prescribed for a week or a fortnight, and the effect on the heart rate recorded by frequent pulse counts at two- or four-hourly intervals, and by daily electrocardiograms. Six casts of complete heart-block were tested in this way.

As a further measure of the efficacy of ephedrine it has been administered at intervals to two patients for over a year, both of whom suffered from complete heart-block and had been accustomed to fairly frequent seizures. Actually, this method would seem to be the more desirable test of the two, but when attacks of any kind appear only at rare and infrequent intervals the effect of treatment directed at their prevention is difficult to assess. It is not uncommon to find that even frequently repeated Stokes-Adams seizures may cease spontaneously for no very obvious reason. *Vis medicatrix naturae* must always complicate therapeutic deductions.

EFFECT OF EPHEDRINE AND BARIUM ON VENTRICULAR RATE

In four of the six patients ephedrine taken orally brought about and maintained a definite acceleration of the ventricular rate. In the two remaining individuals (Cases 2 and 4) the test was indecisive. Case 2 was that

of an elderly man with a relatively high ventricular rate (46 per minute) in an advanced degree of congestive heart failure. Adrenaline has but little accelerating effect on the ventricles at such a rate,⁴ and it may be for similar reasons that ephedrine (in 1-grain doses, thrice daily for six days) was apparently ineffective in this man. In Case 4 the test was vitiated by the patient's insisting on leaving his bed during the period when the drug was being given. It was therefore not possible to discriminate between the effects of increased bodily activity and any sympathetic stimulation induced by ephedrine. Both these cases may therefore be dismissed and regarded as negative results.

Barium chloride was taken by mouth for several days by the four patients (Cases 1, 5, 10, and 14) whose ventricles were accelerated by ephedrine. Although proved to be susceptible to sympathetic stimulation, no demonstrable effect was produced on the ventricular rate by barium chloride in these four individuals. The response of these cases may now be examined in a little more detail.

Case 1

The patient is an active woman, who had a number of Stokes-Adams seizures between 1923 and 1926. Alive and well at the present time, she has been under observation since 1928, and has had no further attacks. The effect of 1/2 grain doses of ephedrine, twice daily, over a period of eleven days was tested in November, 1928. It increased the ventricular rate by an average of 4 beats per minute throughout the period of its administration, the maximum rate in the control period being 28 per minute. For two days she received 40 mg. of barium chloride at six-hour intervals, and then 60 mg. for the succeeding nine days. No change in the pulse rate, blood pressure, or form of the electrocardiogram was observed.

Case 5

The patient, a man, has been under observation as a case of complete heart-block since August, 1931. One Stokes-Adams seizure occurred in December, 1930. There have been no further attacks, and he keeps well and reasonably fit for work. Ephedrine was given in increasing amounts over a period of eleven days, commencing with 1/2 grain twice a day and rising to 1 grain four times a day (see Fig. 1). The ventri-

FIG. 1.—Shows the effect of the oral administration of ephedrine on the pulse rate in Case 5. The daily maximum and minimum of two-hourly pulse counts are recorded.

cular rate increased from a maximum of 28 in the control period to 46 during the time the drug was taken. Thereafter the rate gradually declined during the succeeding days. At a later period he received 240 mg. of barium chloride for three days, followed by double this amount for a further period of three days. No effect on the rates of auricles or ventricles was recorded. Extrasystoles were not detected.

Case 10

The patient was an elderly woman, who had one severe Stokes-Adams seizure on the day of her admission to hospital. She died two months later of hypostatic pneumonia without experiencing another attack, although she had had at least 352 typical attacks in the previous twenty months. The pulse rate ranged from 28 to 32 during the control period. Ephedrine in 1/2 grain doses, four times in the twenty-four hours, produced no appreciable effect, but on doubling the dose the rate varied from 32 to 36 during the four days on which this amount was taken. The rate returned to its pre-existing level within thirty-six hours. Barium chloride was tried in larger doses than in the previous cases. For three days

fell from 250 mm. Hg during complete block to 210 during the three to one rhythm. Ephedrine was abruptly discontinued on the night of May 31st.

A remarkable series of symptoms arose within twelve hours of discontinuing the treatment with ephedrine. In the early hours of the following day (June 1st) she complained of headache and pains in the back, and suffered from two fainting turns of no more than a few seconds' duration. During the forenoon the heart rate gradually declined. At 11 a.m. the ventricles were beating at a rate of 16 per minute, and she complained of increasing weakness. At 11.55 a.m. the rate was 11 per minute. At 12.15 p.m. it had declined to 9 beats per minute (Fig. 4). She was pale, with slow, sighing respira-

FIG. 2.—Displays an electrocardiogram of a mild Stokes-Adams attack recorded in Case 14 on July 2nd, 1931. The period of ventricular arrest measures 9.8 seconds, and is preceded by two to one block and followed by three to one. Ephedrine was effective in abolishing these seizures.

she received 60 mg. thrice daily, increased to 90 mg. for a similar period, and finally 120 mg. thrice daily for six days. No appreciable alteration in the rate of the pulse was observed, though occasional extrasystoles were recorded.

A TOXIC EFFECT ATTRIBUTED
TO EPHEDRINE

Case 14

The patient was an obese woman, aged 61, who in 1930 suffered from dyspnoea and was found to have a persisting two to one block (P-R interval 0.18 second). In June, 1931, she began to have repeated syncopal attacks due to ventricular arrest (Fig. 2), the block being either two to one (P-R interval 0.185 second) or three to one (P-R interval 0.165 second). By April, 1932, electrocardiograms demonstrated a complete dissociation of auricles (rate 70) and ventricles (rate 28), and syncopal attacks were infrequent. In May, 1932, her response to ephedrine was tested. At this time she complained of repeated frontal headaches, general weakness,

FIG. 3.—Shows the effect of ephedrine on the pulse rate in Case 14 in May, 1932. The ventricular rate increased from 30 to 36, and four days after commencing the drug a three to one block replaced the complete block formerly present. The ventricular rate fell to 7.5 per minute on suddenly discontinuing the drug's administration.

FIG. 4.—Shows an electrocardiogram recorded in Case 14 on June 1st, 1932, sixteen hours after discontinuing the administration of 3 grains of ephedrine per day. The ventricular rate is 8.5 beats per minute. The auricular rate is 82.4.

and great exhaustion on the least bodily exertion. She was, in consequence, confined to bed for three months. For one week she received daily 120 mg. of barium chloride, and for a second similar period double this amount. No change was observed in the rate of the ventricles or in the electrocardiograms. Extrasystoles did not occur. Ephedrine in 1/2 grain doses, four times a day, was commenced on May 26th. It produced an increase in the ventricular rate from 30 to 36, as demonstrated in Fig. 3; but four days after commencing the drug a regular three to one block, with a P-R interval of 0.395 second, replaced the complete dissociation formerly present. The systolic blood pressure

was, in consequence, unable to make the least bodily exertion, and was semi-conscious, but sufficiently well to ask for nourishment. At 12.35 p.m. she complained of nausea, and immediately afterwards lost consciousness in a typical Stokes-Adams seizure. She was quite unconscious for one and a half minutes, during which time the ventricles continued to beat at a rate of 7.5 per minute. Recovery was gradually accomplished by a spontaneous increase in ventricular rate, first to 10 and then to 15 beats per minute. Between 1 and 2 p.m. she had three further seizures, each of which resembled the first in that the ventricles continued to beat throughout the attack at a rate of approximately 7 or 8 per minute. A subcutaneous injection of 0.5 c.c. adrenaline abolished the attacks by increasing the ventricular rate to 23 per minute and inducing four to one block. A further course of ephedrine restored three to one rhythm. She gained rapidly in health and was discharged from hospital, taking 1 grain of ephedrine thrice daily.

These alarming symptoms, which immediately followed the abrupt withdrawal of ephedrine (and were later abolished by its continued administration) suggests that over-stimulation was a cause for the exhaustion of the few remaining conducting strands in the bundle of His, and also of the rhythmic centre controlling the independent ventricular beat. When the drug was discontinued conduction failed, and the transition from high-grade partial to complete block was rendered dangerous by a progressive slowing in the idioventricular rate. As a general principle it would appear desirable to use the minimum

quantity of ephedrine capable of increasing the ventricular rate, as larger doses may, at least in certain cases, cause over-stimulation and later exhaustion of the idio-ventricular centre.

EPHEDRINE IN TWO CASES OF STOKES-ADAMS SYNDROME

Of fourteen patients with complete heart-block under observation only two were accustomed to have seizures at sufficiently frequent intervals to warrant a fair test of the efficacy of ephedrine in their prevention.

Case 4

A patient (Case 4, referred to above) came under observation in April, 1932, suffering from complete heart-block with a history of repeated Stokes-Adams seizures at intervals of from three to six weeks for three years. Ephedrine in 1/2 grain oral doses thrice daily was commenced on July 2nd, 1932, and continued until October 31st, 1933. Not one seizure was experienced during these sixteen months. The drug was discontinued on November 1st, 1933, and he remained well and free from attacks for seven weeks, when a single seizure again took place. He recommenced taking the drug the following day, and from December 22nd, 1933, until February 5th, 1934, when last seen, he has had no further attacks.

Case 14

Another patient (Case 14) was admitted to hospital on June 25th, 1931, and that evening there were several "fainting attacks" in succession. Single attacks occurred on June 26th, 29th, and 30th. On July 1st there were about half a dozen attacks, and on the next day about twenty seizures were observed in the course of an hour or two. Fig. 2 demonstrates a period of ventricular asystole lasting 9.8 seconds, preceded by two to one block and succeeded by three to one. Adrenaline, 0.5 c.c.m. subcutaneously at 2 p.m., was followed by freedom from attacks until 5 p.m., when two similar fainting turns were experienced. Ephedrine was begun in 1/2 grain doses by mouth four times a day at 6 p.m. that evening. No seizures were observed or complained of on July 3rd, 4th, or 5th. Ephedrine was discontinued at 8 p.m. on the 5th, and at 6 a.m. on the following day there were three minor attacks. The drug was recommenced on the evening of July 6th, and continued until her discharge from hospital on July 18th, 1931. On the 8th and 9th two short attacks were complained of, at about 8 a.m. on each occasion. By rearranging the times of administration of the drug no further attacks arose.

It seems reasonable to conclude that ephedrine played a part in the prevention of seizures in this woman, probably by facilitating conduction (though the block remained two to one) and increasing the excitability of the ventricular muscle. She voluntarily gave up taking the drug about January, 1932, and between then and April, 1932, when she was again admitted to the ward, she had several seizures. The block being complete, her response to ephedrine was tested in May, 1932, as described previously, when toxic effects supervened on its sudden withdrawal. She was discharged from hospital on June 15th, 1932, and from that date until the end of July, 1933, she took 1 grain thrice daily. She had no attacks during this time. During August, 1933, she was persuaded gradually to give up its use. After discontinuing it she had three seizures in four weeks. From September 1st, 1933, until January 30th, 1934, taking 1/2 grain thrice daily, she has had no further attacks, and refuses to make any further reduction in the dose. Electrocardiograms show that the block is complete, and the usual ventricular rate 30 per minute.

Both these cases point strongly to the efficacy of ephedrine as a means of preventing Stokes-Adams seizures. During its administration syncopal attacks ceased. When its use was abandoned seizures returned. No ill effects were observed when it was being taken; on the contrary, both individuals have now a much greater response to effort than formerly, and each, unknown to the other, attributes improvement in health and well-being to the drug. In Case 4, after eighteen months' treatment, the patient is now able to enjoy a walk of four to five miles over the rough country of the Pentland Hills. In

Case 14 the patient can do housework, which she was formerly forced to decline.

Barium chloride has not been tested under similar conditions, as from the earlier observations it was evident that, in spite of larger doses than those recommended, it did not appreciably alter the rate of the ventricles. It may be that it acts by increasing their irritability without a decisive change in rate, and that in certain cases barium might enhance the response to ephedrine. Employed alone, it can hardly be expected to compete with ephedrine as a remedy for the prevention of occasional seizures. It is perhaps too much to hope that ephedrine will prove effective in all cases of the Stokes-Adams syndrome. If attacks recur despite adequate dosage, then it would seem reasonable to combine it with barium chloride.

SUMMARY AND CONCLUSIONS

In six cases of complete heart-block ephedrine taken orally increased the rate of ventricular beating in four. In two patients the test was indecisive.

Barium chloride produced no demonstrable effect on the ventricular rate in the four cases responding to ephedrine. It did no harm in doses larger than those originally recommended.

In two cases of complete heart-block, complicated by occasional Stokes-Adams seizures, ephedrine taken for two and a half and one and a half years respectively proved entirely successful in the prevention of syncopal attacks. When the drug was discontinued typical seizures returned.

It is recommended that the dose of ephedrine should be the minimum quantity consistent with an acceleration of the resting ventricular rate. Larger doses may cause over-stimulation. If the drug be then suddenly omitted, profound slowing of the ventricular rate, with repeated Stokes-Adams attacks, may occur, as a result, presumably, of exhaustion of the idioventricular centre. A dose of 1/2 grain by mouth at eight-hour intervals may be sufficient.

In the absence of positive findings it is difficult to credit barium chloride with the power of preventing Stokes-Adams seizures.

My best thanks are due to Professor Murray Lyon, who has given me the opportunity of having all these cases under observation in his wards in the Royal Infirmary. To Dr. Edwin Matthew and Dr. Alexander Goodall I am also indebted for their kindness in placing patients at my disposal for this investigation. Dr. P. Martin Brodie and Dr. George Brewster kindly referred cases to me.

TRANSIENT MASSIVE ALBUMINURIA AFTER CHROMOCYSTOSCOPY IN A PSYCHO- NEUROTIC INDIVIDUAL

BY

F. PARKES WEBER, M.D., F.R.C.P.

SENIOR PHYSICIAN TO THE GERMAN HOSPITAL

I have not succeeded in finding any account of a case in which cystoscopy or chromocystoscopy was followed by transient massive albuminuria as it was in the case reported below. But then the urine is not usually examined in this way twenty-four hours after a cystoscopy, and by another twenty-four hours the albuminuria had almost completely disappeared. I can find no published clinical or experimental support for my idea that the massive albuminuria represented an idiosyncratic reaction towards the intravenous injection of indigo-carmin. The non-appearance of the colour in the urine after the injection of indigo-carmin has usually been regarded as a bad sign, but presumably in the present case the indigo-carmin was excreted in the urine after having undergone transformation into a colourless substance. This need not have had any connexion with the subsequent transient massive albuminuria. I am much indebted to Mr. T. Dietzsch for his kindness in referring me to data about indigo-carmin.

One cannot help thinking of the massive albuminuria which has been observed occasionally after cerebral haemorrhage. J. Sabrazès and Ch. Massias in 1923 (abstract in the *Presse Médicale*, Paris, 1923, xxxi, 104) drew attention to such "massive" albuminuria, without tube-casts, in cases of cerebral haemorrhage. They found that in a young rabbit, when 2 to 3 c.cm. of its own blood was injected into its brain, albuminuria accompanied the resulting apoplectic shock, the albumin in the urine reaching 4.6 per mille at the time of the animal's death, thirty hours afterwards. In connexion with the same subject one might also compare some of the phenomena of attacks of acute "angioneurotic oedema."

RECORD OF CASE

The patient, a well-nourished woman aged 26 years, was admitted to hospital on November 9th, 1933, on account of uncertain abdominal pains. For nearly ten years she had been troubled with frequent micturition during the day, but not (or much less) during the night. This pollakiuria had been supposed to be of psychoneurotic origin (in Germany) as early as 1925, but at that time there seems to have been evidence likewise of a *Bacillus coli* infection. Psycho-analytical treatment at Zürich and elsewhere is said to have had a beneficial result. In March, 1933, she commenced to complain of abdominal pains, and in September appendicectomy was performed for "chronic appendicitis"—but without relieving her main symptoms.

On November 9th, 1933, she was therefore admitted on the medial side of the German Hospital. Apart from somewhat vague abdominal pains and the pollakiuria, hardly anything abnormal could be discovered. By Roentgen-ray examination of the abdomen, two or three calcified lymph glands were evidenced. Nothing abnormal was found in the thorax. The urine (catheter specimen) showed a cloud of albumin, and the centrifuge sediment contained a few leucocytes and erythrocytes, but no tube-casts. Brachial blood pressure: 120/74 mm. Hg. Nothing abnormal by ophthalmoscopic examination. A Pirquet cuti-reaction gave a weakly positive reaction, as it does in most normal adults. Menstruation had commenced at 14 years of age, and had always been normal. There was a history of longevity on both sides of the family.

In order further to investigate the cause of the slight albuminuria and the source of the erythrocytes in the centrifuge sediment of the urine, a chromocystoscopy was kindly undertaken on November 14th by my colleague, Mr. A. Compton. It was, however, impossible to find the orifices

of the ureters, and therefore the ureters were not catheterized. The indigo-carmin (4 c.cm. of a 0.4 per cent. solution) injected intravenously was not observed to reappear in the urine. The mucous membrane of the urinary bladder was seen to be intensely congested, possibly as a reaction towards the irritation of the examination.

This cystoscopic examination (none had been previously made) was followed by some local pain, which, however, left her in two hours or so. But next morning (about twenty-four hours after the cystoscopy) her urine was found to be loaded with albumin (10 per mille by Esbach's tube), and, though it was not coloured with blood, the centrifuge sediment contained many erythrocytes and leucocytes; no tube-casts seen. A day later (November 16th) the urine showed only a thin "cloud" of albumin; there were a few leucocytes and a very few erythrocytes in the centrifuge sediment and (as before) no tube-casts. No culture of *Bacillus coli* could be obtained from the urine (November 22nd and on a previous occasion). In the hospital the pollakiuria was not accompanied by polyuria, and before she left (November 25th) the former was greatly diminished—possibly partly owing to her psychic condition having been entered into. Moreover, the patient altogether felt better.

DIABETES AND ULTRA-VIOLET IRRADIATION THERAPY

BY

NOAH MORRIS, M.D., B.Sc., F.R.F.P.S.G., D.P.H.

AND

D. CAMPBELL SUTTIE, M.C., M.B.,
F.R.C.S.E.D., D.P.H.

(From the Department of Paediatrics, Glasgow University, and
the Biochemical Laboratory, Royal Hospital for
Sick Children, Glasgow)

During the past twelve years reports have appeared in the literature regarding the beneficial effects of ultra-violet light irradiation on sugar tolerance and hyperglycaemia in diabetes.

Pineussen¹ found that irradiation produced definite improvement in a series of diabetic patients with regard to level of blood sugar and excretion of glucose and acetone. He gave no details of the clinical condition of the patients apart from the diagnosis of diabetes mellitus, but stated that those diabetics who had marked polyuria (hypophyseal diabetes) showed no improvement. Andersen² recorded a beneficial result in the treatment of one diabetic patient whose sugar tolerance increased from 24 to 96 grams of carbohydrate, and whose fasting blood sugar fell from 100 mg. per cent. to 70 mg. per cent. immediately after irradiation. Saidman³ has reported benefit from the use of ultra-violet irradiation in five patients, in two of whom a mild glycosuria completely disappeared. He considered that ultra-violet treatment was indicated in glycosuria associated with entaneous manifestations, dental lesions, and malnutrition, and also in severe diabetes where insulin was necessary. Rothmann⁴ has given records of two diabetic patients treated with ultra-violet light. One with acne rosacea responded favourably, with disappearance of acetonuria and glycosuria (5.3 grams glucose daily) and a fall of fasting blood sugar from 183 to 120 mg. per cent. The other, who had generalized eczema, showed no improvement after ninety-five days, both blood sugar and glycosuria tending to increase. A patient of Rollier (quoted by Furniss⁵), aged 45 years, with benign diabetes mellitus of many years' standing and easily controlled by dieting, was able, after natural sunlight treatment, to live on ordinary hotel diet without glycosuria: after twenty-four hours without a sun-bath all the symptoms reappeared. J. Wilson,⁶ after a brief résumé of the literature, stated that all workers found decrease of glycosuria and acetonaemia after ultra-violet irradiation of diabetic patients: he considered this treatment specially suitable for diabetes complicated by neuritis, carbuncles, and vasomotor and trophic disturbances. Rothmann⁷ also obtained good results in a case of diabetic xanthomatosis: in another diabetic with

pruritus the skin irritation disappeared after ultra-violet irradiation, although the fasting blood sugar rose from 140 to 210 mg. per cent.

All the reports in the literature that we have obtained have dealt with adults, and on the whole have been favourable. It is noticeable, however, that many of the patients successfully treated have had pathological conditions of the skin. In view of the well-known fact that sunlight has a marked effect on the development of children it seemed advisable to determine whether ultra-violet light influenced their sugar tolerance and insulin requirements. As diabetes in childhood is not usually complicated by other diseased conditions, such as arteriosclerosis or tuberculosis, it was hoped to decide whether the improvement observed in adults was the result of direct action on the carbohydrate-regulating system, or of a secondary effect due to alleviation of some other pathological condition such as skin lesions.

SCOPE OF INVESTIGATION

The immediate effect of irradiation on blood sugar was investigated in a few normal and diabetic children. Blood was withdrawn prior to, and immediately after, irradiation lasting two minutes. The children were in the post-absorptive state, having refrained from food for at least six hours previously. Table I shows some of the results obtained.

TABLE I

Name	Age in Years	Condition	Blood Sugar	
			Before Irradiation	After Irradiation
A. R. . . .	8	Non-diabetic	mg. per cent. 66.0	mg. per cent. 58.0

J. P. . . .	11½	"	169.0	153.8
J. L. . . .	8	"	103.0	117.6

Ultra-violet irradiation of five non-diabetic subjects produced in four an immediate fall of blood sugar and in one a rise, while irradiation of six diabetic patients on ten occasions led to an immediate fall in blood sugar on five, a rise on four, and no change on one. It is evident from these figures that irradiation may cause an immediate increase or decrease of the blood sugar both in non-diabetics and in diabetics. Furthermore, different results were obtained on different days with the same patient. These findings differ somewhat from those of Lucca and Reviglio,* who reported that in children after irradiation with infra-red or ultra-violet rays the sugar content of the blood was always diminished, though there were individual variations in the decrease.

Despite these conflicting results it was determined to study the effect of a course of ultra-violet irradiation on carbohydrate tolerance in a series of diabetic patients.

MATERIAL TESTED

The subjects of the test were regular attendants at the diabetic clinic of the Royal Hospital for Sick Children,

Glasgow. All had been attending for at least six months, and some for five or six years. Their dietary and insulin requirements were fairly accurately known. The mothers of the children were all intelligent, and had been co-operating successfully with us. The possibility of improving sugar tolerance by ultra-violet therapy was explained to the mothers of all the children attending the clinic, and those that desired to try out the effect of this treatment did so enthusiastically, in the hope that the treatment might permit a decrease in the dose of insulin. The children of the more sceptical mothers acted as controls.

In all ten children (ages varying from 7½ to 14½ years) received ultra-violet therapy, and four (aged 2½ to 13 years) did not. The treatment was given twice weekly; at first one-minute exposures were given to the whole thoraco-abdominal region, dorsal aspect of the body, and limbs (small slips being worn and goggles). Gradually the exposures were increased by thirty seconds every week until three-minute exposures were given. The source of light was a mercury vapour vacuum burner (new) 250 volts D.C. Five minutes was allowed after lighting to permit the output to settle. The distance of the exposed area from the source of light was 36 inches. When pigmentation was observed the therapy was stopped for an interval, as most workers are agreed that pigmentation lessens the therapeutic effect. (Rothmann* states that when pigmentation occurs the blood sugar begins to rise.)

RESULTS OBTAINED

The following tables give a brief résumé of the results after ultra-violet irradiation had been given. The carbohydrate tolerance was estimated from the amount of total carbohydrate—that is, carbohydrate plus half the protein—utilized per unit of insulin. The weight and height were calculated as percentages of the expected weight and height respectively.

TABLE II

Name	Age in Years at July, 1932	Carbohydrate Tolerance		Percentage Expected Weight		Percentage Expected Height	
		Before	After	Before	After	Before	After

J. P. . . .	11½	2.5	2.4	97	87	91	97

* These patients did not receive ultra-violet irradiation therapy.

The carbohydrate tolerance improved in four out of the ten patients given ultra-violet therapy. The same proportion was found when the estimation was based on the absolute amount of insulin required, four patients requiring less insulin at the end of the year. In six patients, however, the tolerance diminished. Although the proportion with decreased tolerance was greater in those not receiving ultra-violet irradiation the numbers are much too small to make this difference significant.

The incidence of infection in the two groups was also noted with special reference to the occurrence of glycosuria. In the ultra-violet irradiation group three of the patients had mild infections—for example, nasal catarrh with or without mild pyrexia—and four had moderately severe attacks—influenza, adenitis, scarlet fever. Two of the latter four had to be admitted into hospital because of diabetic acidosis. Of the control group one patient had a mild enteritis and two had moderately severe attacks of adenitis necessitating their admission to hospital because of impending coma.

TABLE III*

	Total No.	Carbohydrate Tolerance			Percentage Expected Weight			Percentage Expected Height		
		Improved	No Change	Decreased	Improved	No Change	Decreased	Improved	No Change	Decreased
Receiving U.V.R. ...	10	4	—	6	4	1	4	—	2	7
Not receiving U.V.R.	4	1	—	3	1	1	2	—	1	2

*Cases receiving U.V.R.—data of height and weight from only nine cases. Cases not receiving U.V.R.—data of height from only three cases.

As regards other effects of the treatment, the mother of one patient stated that about one hour after irradiation the boy felt very limp, and that sugar had occasionally to be given because of the threat of hypoglycaemia. This particular patient was one whose carbohydrate tolerance per unit of insulin was reduced at the end of the year. Another patient (a boy of 13 years) stated that he felt better after ultra-violet irradiation treatment was commenced: in this case it had been noticed in previous years that during long spells of bright weather in the summer the insulin had to be reduced owing to a tendency to hypoglycaemic attacks.

SUMMARY

The effect of ultra-violet therapy on sugar tolerance, insulin requirements, growth, and general health was determined in ten diabetic children, aged $7\frac{1}{2}$ to $14\frac{1}{2}$ years, over a period of one year. The results, compared with those of a control series of four children who did not receive ultra-violet therapy, showed no significant improvement that could be attributed to the irradiation.

We should like to express our thanks to Professor G. B. Fleming for his interest in this investigation, and to the Medical Research Council for a personal grant to one of us (N. M.).

A CASE OF AXILLO-BRACHIAL
EMBOLECTOMY

BY

G. E. LARKS, CH.M., F.R.C.S.ED. AND ENG.
SURGEON AND MEDICAL SUPERINTENDENT, PLYMOUTH CITY HOSPITAL

The paucity of references in this country to the subject of arterial embolectomy suggests that the record of a single successful case is still worth the making.

CASE RECORD

A retired male railway worker, aged 64, was admitted to the Plymouth City Hospital complaining of vague abdominal pains and recently developed constipation. His history was one of good health, except that he had had a perianal abscess two years previously, and "phlebitis" in the right popliteal region six weeks before admission. Nothing abnormal could be detected in the popliteal region. He was well nourished, of a full-blooded appearance. Radiological evidence of carcinoma of the upper end of the sigmoid colon was obtained, and this was confirmed at operation on July 25th, 1933. Abdominal section by a paramedian incision was made and the growth located, through a left lateral oblique muscle cutting incision it was widely mobilized, and the first stage of a Paul-Mikulicz resection was performed. On August 5th, 1933, eleven days after operation, the patient complained of a sudden loss of power in the right arm and hand, accompanied by tingling pain and numbness. This occurred while he was washing himself. I saw him at 11 a.m., when he was still complaining of pain and numbness, and was rubbing the limb "to improve its circulation." The whole limb distal to the middle of the arm was pale and cold, with a blotchy cyanosis in the upper part of the cold area. The radial pulse was impalpable, the brachial pulse could not be felt or heard at the elbow or in the arm, but about the level of the termination of the axillary artery a forcible pulse could be felt.

At 11.30 a.m., five hours after the onset, under local anaesthesia, the artery was exposed by an incision along its course, care being taken to preserve branches. The artery was mobilized; the site of lodgement of the embolus was easily detected, just proximal to the offset of the profunda artery. There was a local increase in the diameter of the non-pulsating axillo-brachial artery for about 1½ inches. Proximal to this the axillary artery seemed to beat unusually powerfully; distally lay the brachial artery, contracted and pulseless. Light intestinal clamps, rubber-covered, were gently applied above and below the embolus, and a small incision, 1/3 inch or so in length, was made into healthy artery above the upper end of the embolus, which was immediately partially extruded. It was carefully withdrawn. The distal clamp was released, and blood flowed from the distal end. The proximal clamp was then released somewhat, and blood flowed freely. With the clamps again controlling, the incision in the artery was closed by three mattress sutures of paraffined silk evertting the edges of the wound, and apposing the intima, and narrowing the arterial lumen as little as practicable. Throughout the operation the wound was sponged occasionally with 2 per cent. sodium citrate.

The clamps were released, and a good pulse was immediately palpable at the elbow, and a definite though less forcible pulse at the wrist. The wound was closed and healed perfectly. No splint was used, but the limb was swathed in wool. Shortly after operation the limb was definitely warmer, and twelve hours after operation there was a warm limb of apparently normal colour, with a radial pulse of good quality, though somewhat less forcible than that of the other arm. The pulse remained of good quality and the limb of normal appearance. At the present time, twenty-three weeks after operation, the right radial pulse is slightly less forcible than the left; there is, however, no difference in appearance or function between the two limbs.

Since the arterial operation the patient has undergone two further operations to restore the continuity of the intestine. Less drastic measures failing to produce closure of the colostomy, excision with end-to-end anastomosis was performed. He is now in good general health, and living his normal routine of retired life.

COMMENTS

There is a steadily increasing literature, mainly Scandinavian and American, concerning embolectomy. Of 216 operations culled by Einar Key¹ in 1929, from his own experience and the literature, 145 were Swedish. There were eighty-six successes. In 1922, in a pioneer paper which stimulated interest and activity in embolectomy, Key² had gathered thirteen successes out of forty-five cases. He states that to Ssabanagew (1895) is usually credited the first attempt, though unsuccessful; and to Labej the first success in 1911.

Emboli are somewhat less common in the upper than in the lower extremity. Curiously, Jefferson's³ case—the first success in England and recorded in 1925—a case published by A. Gray Banks⁴ in 1931, which I was fortunate enough to see, and the case here recorded were all in the upper extremity; all were also post-operative occurrences.

The diagnosis presents no difficulty. The sudden onset of tingling pain, numbness, and loss of power, with waxy pallor, coldness in the limb, and absence of the pulse make the diagnosis obvious. The absence of warmth and oedema excludes venous thrombosis, and a nerve lesion needs only to be considered to be immediately excluded. It is noteworthy that the accompanying pain is often very severe. The embolus tends to lodge at the site of the giving off of a large branch (in this case the profunda), or a bifurcation. If the site is accessible a swelling may sometimes be felt in the line of the artery. The stethoscope may help to localize the block by auscultating along the vessel towards the obstruction.

When exposed at operation the picture is unmistakable: a local swelling with the vessel thin and contracted beyond it, and proximal to it beating powerfully in a manner that recalls the downward thrust of a main limb artery ligated in an amputation. The operation follows the usual lines of arterial surgery. While special arterial clamps are helpful they are not essential; and no instrument is called for that is not usually available in every theatre. In addition to the materials for arterial suture, it is advisable to have a suitable soft rubber catheter in paraffin, to which a syringe containing 2 per cent. sodium citrate, can be attached. The arteriotomy wound can then be flushed, if necessary, to get rid of small adherent particles of thrombus. There is no agreement as to the best site at which to open the vessel. Incision immediately proximal to the clot, if anatomically convenient, has the advantage that it is through healthy artery of convenient size for suture. The embolus may extrude itself, as in this case, or may need to be "milked out," or extracted with forceps. In closure intimal apposition is secured by everting the edges of the arterial wound with a mattress suture, which may be interrupted or continuous.

The recorded cases show that the time factor is of paramount importance in prognosis. Andrews and Harkins⁵ believe that operation after ten hours is usually too late to save the limb. Danzis⁶ stresses the time factor, and points out that in early cases 60 per cent. of good results may be expected, but that even at the end of twenty-four hours operation is not too late to lessen the chances of gangrene arising, or of removing the site of gangrene further distally than it would otherwise have been. Neuhoof⁷ holds that the symptoms of vascular occlusion are due to the thrombus which forms in relation to the embolus, and that "early" operation is not really so early after all. In both the successful cases I have seen, however, the onset was apparently sudden, and gave no warning symptoms of impending vascular occlusion such as a developing thrombus might be expected to show.

There is no real doubt that early operation is imperative, and that the condition is one of real urgency: recognition of this may save many a limb. No conditions could have been more favourable than those in the cases of Jefferson, Gray Banks, and in the ones recorded above; in each case there was a single embolus occurring in a patient, apparently in good general health, during post-operative convalescence in hospital.

SOURCE

The recorded cases divided themselves into two main groups: (1) those in which a cardiovascular lesion exists, and (2) post-operative or post-parturition. A few occur in acute infections. Jefferson emphasized the important part played by the heart as a source of small emboli, either from vegetation or intracardiac thrombosis. There seems little doubt that mural thrombi are not uncommon, and it is probable that they are more prone to occur with cases of infection or following operation. An origin from systemic veins or the right heart postulates the existence of a patent foramen ovale. There was no clinical evidence of heart disease in this case.

In this connexion it may be of interest to mention a case which I have seen since, of embolism of the popliteal artery, in which the probable source was demonstrated at necropsy. The man was 66, and moribund with cardiorenal failure. The left leg became cold, and no pulse could be found in the popliteal anterior or posterior tibial artery. No lump was palpable over the line of the artery, but by auscultation I was able to locate the block about the level where the artery passes through the adductor magnus to the back of the limb. The patient was only a few hours from death, so no operation was attempted. At necropsy I found the block at the level indicated, and in the ascending aorta an atheromatous plaque, 3/4 inch in diameter, which was ulcerating and partially free, and bearing on its surface a thin, shaggy, fibrinous layer—I think almost certainly the source of the embolus. A splenic infarct was also present.

On his retirement, after thirty-eight years' service as medical officer of health for Portsmouth, Dr. A. Mearns Fraser has received a personal tribute in the form of a cheque from a large number of subscribers. Sir Thomas Bramsdon, who made the presentation, remarked that at Dr. Fraser's appointment in 1896 he was the youngest medical officer of health who had ever held so important an office, and he had held it longer than any other in the United Kingdom. Under his guidance Portsmouth had attained a position second to none in the country as regards health matters, while Southsea had won a deservedly high reputation as a coast resort. Another important reform which Dr. Fraser had assisted in promoting was the inspection of meat, and the drawing up of regulations, which had been widely adopted. He had taken an active part in pressing for the clearance of slum areas, and for the purification of the Portsmouth water supply. In 1912 he had been invited by Mr. Lloyd George to become a member of the original Departmental Committee on Tuberculosis. Of its seventeen members only two were medical officers of health. A further activity of his was the drawing up of special regulations for the control of venereal diseases. Previous appreciatory gifts had been made to Dr. Fraser by the Lord Mayor and Corporation, the Health Committee, the Corporation officers, and the Portsmouth Midwives Association.

INJURIES TO FEMORAL VESSELS DURING
HERNIA OPERATIONS

BY

F. T. RANSON, M.B., B.Ch.BELF., F.R.C.S. Ed.

SHANGHAI

Most surgical textbooks mention the possibility of injury to the external iliac or femoral vessels during operations for hernia, but even in the larger textbooks the matter is dismissed in a few lines, and no account of treatment or sequelae is given. These injuries must be extremely rare; many surgeons of considerable experience to whom I have spoken have never seen or known of a case. Burrows¹ says that he has once seen the external iliac artery wounded, but he does not give details. He gives a reference, however, to the *British Medical Journal*, (1914, ii, 115), where O'Connor mentions two cases in which he himself injured the external iliac vein: a Chopart amputation was the penalty in one case; there was no penalty in the other. Coley² states that from personal communication he knows of four cases of injury to the large vessels during the insertion of deep sutures into Poupart's ligament. Thorek³ deals with the subject briefly, and gives but little information.

The best account of these injuries that I have been able to find is by Stich and Makkas,⁴ in their book on surgical errors. Although the surgeon is usually apprised of the fact that damage has been done to a large vessel by the copious haemorrhage which takes place, yet these authors say that the accident sometimes is unnoticed, as no bleeding occurs at the time, and they refer to two cases illustrating this. In one a man died of pulmonary embolism on the ninth day after an operation for inguinal hernia, and it was found that the femoral vein had been perforated. Burrows suggests that some cases of thrombosis after operations for hernia may be due to misadventures with the needle. In the other a patient returned to the clinic two months after a similar operation, with a small pulsating swelling below Poupart's ligament. This was exposed, and was found to be a traumatic aneurysm of the femoral artery. The artery was ligated and the sac excised; a hole the size of a lentil was found in the vessel wall, and the hole was traversed by a stout silk thread. In neither case was there any undue bleeding at the time of operation.

I have recently heard of a case in which the patient died of pyaemia, the result of injury to the external iliac vein. The following is an account of a case which I had the opportunity to study.

CASE RECORD.

The patient, a male Indian aged 36, was operated on in 1926 by a French surgeon for double inguinal hernia. The hernia recurred on both sides. He consulted me, and on December 14th, 1932, I operated on both sides by the Gallie method. The left side was quite successful, but the right discharged some serum, and, after the operation, a little pus. The hernia recurred in about three months' time. I advised him to wear a truss, but, dissatisfied with his truss and with my advice, he consulted a German surgeon, who again operated on the right side on June 12th, 1933.

I have been unable to obtain accurate details of what happened at that operation; but as a suture was being inserted deep into the wound there was a sudden brisk haemorrhage. This the surgeon attempted to stop by passing a still deeper suture. This simply increased the bleeding, and he finally resorted to packing the wound with gauze. The wound bled freely for several days and became septic, but gradually healed, and the patient was discharged from hospital on August 2nd with a small sinus. He was readmitted on August 7th with a severe haemorrhage, arterial in nature. The wound was again packed with gauze, and a blood trans-

fusion was done. On August 18th he had another severe haemorrhage, and Dr. Bennett, superintendent of the Shanghai General Hospital, who saw him on this occasion, says that the haemorrhage was definitely arterial, and that jets of blood hit the wall two feet away from the bed. The wound was again packed with gauze and another transfusion performed.

On August 20th I was asked to see the case, in consultation, and to perform any further operation which might be necessary. It was explained to the patient that it would probably be necessary to tie the main artery to his limb, and that this carried the risk of gangrene of the foot and loss of the leg. He said he would wait and only have the operation done if he had another haemorrhage. At this stage there was a sinus just below the inner end of Poupart's ligament and a small pulsating swelling. No thrill or bruit could be detected.

On August 30th, at 6 a.m., he had another severe haemorrhage, and I was called to the hospital. I found the patient in the operating theatre, and a dresser was controlling the haemorrhage by digital pressure over a gauze pad, which had been tightly packed into the sinus. I at once administered spinal anaesthesia, and, after exposing the external iliac artery by the extraperitoneal route, tied this vessel. The sinus was then examined, but on releasing the pressure there was free venous haemorrhage. The sinus was at once enlarged, and a small arterio-venous aneurysm found just below Poupart's ligament. To stop the haemorrhage it was necessary to tie both the artery and the vein above and below the sac. As this wound was septic it was left open to granulate. The patient had lost a good deal of blood, and was given a transfusion of 500 c.cm. citrated blood.

Two days later the foot, which had been cold, became discoloured. This discoloration spread rapidly up the limb, and as it was obviously gangrenous the limb was amputated just above the knee on September 14th. After this the patient had some fever and increased pulse rate, but he rapidly improved, and is now completely healed. He has been fitted with an artificial limb.

DISCUSSION

Accidents of this kind have happened in the hands of very expert operators, and it is necessary to know how to deal with them. If, as happens in the majority of cases, the injury is at once followed by haemorrhage, the ideal procedure is undoubtedly exposure and suture of the vessel wall. The very fine needles and thread advocated for experimental work are not necessary. Most operating rooms could, however, supply fine needles and silk such as are used in ophthalmic surgery, and these are quite suitable.

By courtesy of Mr. John Gray, F.R.C.S., of the Henry Lester Institute of Medical Research, I have been enabled to carry out experiments in arterial suture. It was found possible successfully to suture incisions in both the aorta and the femoral arteries of small dogs with Kalt's conjunctival needles and very fine silk. The vessel can be held up by an assistant on tapes or rubber tubes; this gives excellent access, and controls bleeding during the suturing. It is not necessary to use paraffin or vaseline on the needles and thread. Human hair, which is readily available and is easily sterilized, is suitable material, and it is easier to thread these fine needles with hair than with silk. A vessel the size of the femoral artery in man could certainly be securely sutured with these materials.

If, for any reason, suture were impracticable or failed, then it would be necessary to resort to ligation. Authorities differ as to the risk of ligation of the common femoral trunk. Wolf, quoted by Stich and Makkas, says that in 25 per cent. of cases gangrene follows. Rowlands and Turner⁵ stress the risk of gangrene, but Reid and Andrus⁶ state that in the absence of infection one should be able to tie the normal femoral artery in any part of its course with no untoward result. Dr. Loucks, head of the department of surgery in Peking Union Medical College, to

whom I am indebted for helpful comments, is of this latter opinion, and considers that the gangrene which ensued in my case was due to interference with the collateral circulation by infective thrombosis. It is commonly taught that where it is necessary to ligature the main artery to a limb, ligature of the main accompanying vein at the same time will diminish the risk of gangrene, but the results of the experimental work of Wilson⁷ do not support this view.

The treatment at a later date depends upon the conditions present, whether traumatic aneurysm, arterio-venous aneurysm, or haemorrhage. If I were treating a similar case again I would not put a permanent ligature on the external iliac artery, although Lejars⁸ recommends this procedure. It would have been preferable to occlude the vessel temporarily by a special clamp, or by a knot tied over a piece of drainage tubing the calibre of the vessel. As, however, it was necessary to tie the common femoral trunk, and as there was marked infection of the wound, gangrene would very probably have ensued whether the external iliac were patent or not.

Proximal ligature of the external iliac alone has been suggested and has been carried out in similar cases, but it is universally held to be unsatisfactory.⁹ Even though the wound is in the artery alone, the haemorrhage is almost certain to recur; and, naturally, if both artery and vein are involved the measure is useless. Whatever method of proximal control of the circulation be adopted,

the wound must always be explored and the actual bleeding point dealt with.

A colleague informs me that in 1914, in London, he saw the femoral vein wounded during a hernia operation by a well-known surgeon while he was demonstrating to a group of visiting American surgeons. In these embarrassing circumstances the surgeon dealt with the situation very coolly. He said: "Gentlemen, this gives me the opportunity to show you how to deal with this accident," and he proceeded to expose and ligature the vein. The patient made an excellent recovery.

One hopes never to have the misfortune to injure a large vessel; but in the event of such an accident it is well to have a clear idea of the treatment, and to be able to repair the damage by some simple method and with needles and appliances which one might expect to find in most operating rooms, for the needles, suture materials, and special clamps usually described in operative surgery books are unlikely to be at hand in an emergency.

Clinical Memoranda

RESUSCITATION AT BIRTH BY EVE'S ROCKING METHOD

I had been much impressed by the simplicity and ease of the rocking method of artificial respiration described and originated by F. C. Eve.¹ Its physiological soundness was demonstrated in a further paper by Eve and Killick.² Hence I determined to try this method in asphyxia of the newborn when occasion should arise, and such was the case last Christmas Eve.

The mother was debilitated by influenza and had three previous children. Uterine pains were very feeble throughout a long labour. When the cervix had at last dilated the child was easily delivered by forceps—white, and making no attempts to breathe. The heart was just audible with the stethoscope.

I did the rocking in front of the fire, seated, holding the infant on the palms of my hands, face upwards, the legs dangling free, the buttocks being supported and restrained by the left first finger and thumb, the head and neck by the right first finger and thumb. After a few attempts with the child, naked, I covered the trunk in a small towel, which facilitated matters. I found that the fingers adapted themselves to the small body, and that the thumbs and first fingers were used instinctively to check any slipping when the infant was tilted, so that the weight of the viscera alternately pushed and pulled the diaphragm up and down. The rocking movements were performed up and down, about fifteen double "rocks" to the minute (ten are advised). I changed the position of the child to face downwards, but found that was not so easy to manipulate.

After the first minute air was heard coming in and out through the air passages. After twenty-five minutes I put the child into a warm bath, but found that breathing did not go on. It was not until after a total of fifty minutes' rocking that natural respiration was established, when there was some crying, and my task was done.

For general practice, and after a single case only, I consider that Eve's method is an ideal one, and

especially for a very feeble child. There is no violent handling as there may be in other methods of artificial respiration. With supervision it could be performed by anyone of ordinary intelligence, and it could be done in a box-lid, or on the knees with some manipulation. It is a natural method after all, and has materialized from the dawn of the earliest birth—to be adapted by its originator and first published in a scientific paper in 1932. I venture to report this case for publication because I believe it to be the first recorded instance of resuscitation at birth by Eve's rocking method.

FIFTY-ONE STOKES-ADAMS ATTACKS IN FIVE DAYS IN A CASE OF DIPHTHERITIC HEART-BLOCK

It is well known that, at the onset of complete heart-block, attacks of syncope may occur at frequent intervals until the ventricle settles down to beat at its own rhythm. The following case is remarkable for the number and the severity of the attacks.

A boy, aged 17, was admitted to the East Malling Isolation Hospital on October 23rd, 1933, with a history of a sore throat for two days. He was suffering from a very severe attack of faucial diphtheria. The whole of both tonsils, anterior pillars, and uvula were covered with a foul sloughing membrane. There was severe cellulitis and oedema of the neck, which extended over both clavicles and over the sternum to the level of the second ribs. The patient was given 32,000 units of antitoxin, and in three days the swelling of the neck had disappeared. Two days later the throat was clear of membrane, and the acute faucial stage had been safely passed. On the sixth day of the disease (October 26th) albuminuria appeared, which got progressively worse until October 31st, when there was a heavy cloud of albumin, and only twelve ounces of urine were passed. The general condition was fairly satisfactory and the heart normal.

It was on November 1st, the twelfth day, that heart-block appeared, associated with a remarkable series of Stokes-Adams attacks. I saw the patient at 12 noon, and the

¹ *Lancet*, November 5th, 1932. ² *Ibid.*, September 30th, 1933.

matron reported that while he was being washed at 10.45 he fainted. I found the pulse 68 and regular, and no obvious cause for the faint. At 10 p.m. the matron sent for me, but as I was out visiting two urgent cases I did not arrive at the hospital until 12.30 a.m., I was then told that the patient had fainted at 7.15 p.m., and again at 7.30 p.m., and that from 9.30 to 11.30 he had had fainting attacks with remarkable regularity every ten minutes. From 11.30 p.m. until my arrival at 12.30 a.m. the attacks had occurred every five minutes. Since 9.30 no pulse had been felt at the wrist.

I found the patient very pale, in a cold sweat, restless, but quite conscious. No radial pulse could be felt. On auscultation the ventricles could be heard beating feebly but quite regularly at 26 beats a minute. While I was listening the heart stopped suddenly. The patient took a long breath, there was general muscular rigidity for a few seconds, the eyes became fixed, the pupils dilated, the conjunctivae were insensitive, and respiration ceased; he had gone through the usual process of dying. With the stethoscope on the chest and my eye on the watch I heard the heart begin to beat again, after an interval of twenty seconds' silence, at the rate of 26 a minute. Respiration began at once, and consciousness rapidly returned. It was then clear that I was dealing with a case of complete heart-block, with severe Stokes-Adams attacks occurring at regular intervals of five minutes. All the attacks since 7.15 p.m. had been similar to the one I had just witnessed.

The treatment was as follows and in the order given: (1) adrenaline, 10 minims hypodermically; (2) the foot of the bed was raised eighteen inches; (3) camphor in oil, 1 c.c.m. intramuscularly; (4) one pint of saline intravenously. This last was given because the patient had been vomiting and taking fluids badly for the previous twenty-four hours. After half an hour the attacks ceased. At 3 a.m. the pulse could be felt at the wrist at 32 a minute, the colour was much improved, and the patient was sleeping peacefully. I next saw the patient at 10.45 a.m. He had had slight attacks of syncope at 5 a.m. and 7 a.m., and a more severe attack at 9.30 a.m., when 10 minims of adrenaline had been given. The pulse rate had risen to 68 for a brief period at 6 a.m., but was 32 when I saw him. I gave him 1/50 grain atropine intravenously. During the day he had three slight attacks, and three severe ones, when adrenaline was given. The pulse remained between 30 and 40 all day.

On November 3rd there were no further attacks, but 5 minims of adrenaline was given every four hours. The pulse was 24 throughout that day. At 9.15 a.m. he passed three ounces of urine. This was the first urine passed since 3 p.m. on November 1st (forty-two hours), and it contained much less albumin. At 11.30 p.m. ten ounces of urine were passed, and the kidneys appeared to be functioning once again. On November 4th the pulse rate, taken four-hourly, was 24 at 2 a.m., 56, 24, 56, 68, and 58 at 10 p.m. There were eight syncopal attacks in all, and adrenaline was given five times. Twenty-two ounces of urine were passed during the day, which contained a trace of albumin only.

On November 5th the pulse rate did not drop below 50, and there was only one slight fainting attack. Thirty-three ounces of urine were passed and no albumin was present. The patient was altogether better. There was no further heart-block. On some days gallop rhythm could be heard, and there were occasional extrasystoles. Good progress was made up to December 7th, when there appeared a paralysis of the left external rectus. The next day there was a weakness of the muscles to the left of the mouth. The heart was still normal. On December 10th, the fifty-second day of the disease, paralysis of the diaphragm set in, and the patient died suddenly the next day of asphyxia. The heart remained in a satisfactory condition right up to the last.

Summary

A case has been described in which, during the course of a diphtheritic heart-block, fifty-one attacks of syncope were actually witnessed and recorded in the space of five days. Treatment consisted of frequent injections of adrenaline. The heart made a good recovery, but the patient succumbed to diaphragmatic paralysis.

West Malling, Kent.

Reviews

PROGRESS IN ENDOCRINOLOGY

Professor A. T. CAMERON'S *Recent Advances in Endocrinology*¹ is an admirable survey of the subject written more particularly from the experimental and biochemical standpoint. Nevertheless it is very valuable to the clinician, since it states clearly, critically, and succinctly the basis of our knowledge of the endocrine system at the moment. After a brief introduction, in which he shows himself somewhat of a purist in the matter of terminology, the author goes on to an account of each gland in turn, dealing with the biochemistry, physiology, pathology, and then the clinical conditions associated with diseases of the gland in question. A short chapter on secretin and some presumptive endocrine principle follows. Finally, he deals with endocrine interrelationships, subscribing to Cushing's dictum that "all pituitary syndromes are essentially polyglandular." We might indeed maintain the converse of this—that all polyglandular syndromes are initiated by the pituitary.

From such a storehouse of information it is difficult to select material for quotation. We may mention, however, the account of the relationship of iodine to the thyroid, incorporating Harington's most recent observations on the metabolic inactivity of any compound containing less than four atoms of iodine in the molecule, which disposes of the theory that Graves's disease is due to some form of thyroxine unsaturated with iodine. Professor Cameron further gives an interesting account of the control of goitre by iodine in the Pemberton Valley, British Columbia, where it was found that no Indian who ate salmon, an excellent purveyor of iodine, ever developed goitre. This recalls Dr. Woods Hutchinson's humorous description of salmon as "iodide of trout." The goitrogenic influence of cabbage is also well discussed, and is referred to the cyanide, which is a component of its glucoside, diminishing the consumption of oxygen. Marine has injected various organic cyanides into young rabbits and produced goitres, and even exophthalmos. Apparently some abrupt change occurs in the growing cabbage, connected with its maturation, which renders it goitrogenic.

We have said enough to recommend this book very strongly as one of the best, and yet brief, accounts of the subject. The author acknowledges his indebtedness to his former chief, the late Professor Swale Vincent, but, while keenly critical, he shows himself less sceptical than his teacher. There is no doubt, however, that the advance of endocrinology has been actually delayed by uncontrolled speculation and hasty deductions from unproved data, to which Professor Cameron's method of approach is an excellent corrective.

SURGERY OF CHILDHOOD

A famous article in the *Quarterly Review* of some hundred years ago pointed out that one of the main secrets of the art of the reviewer was to read carefully what the author had to say about the purpose of his book, and then scold him for not doing something else. But on reading the introduction to Mr. WILLIAM RANKIN'S *Lessons on the Surgical Diseases of Childhood*,² and then proceeding to the book, it is possible to object that what the author has not done is precisely what he has announced that he will do. These summaries of lectures are

¹ *Recent Advances in Endocrinology*. By A. T. Cameron, M.A., D.Sc., F.I.C., F.R.S.E. London: J. and A. Churchill. 1933. (Pp. 365; 54 figs. 15s.)

² *Lessons on the Surgical Diseases of Childhood*. By D. W. Rankin, M.B., Ch.B. Glasgow: Alex. Macdougall. 1934. (Pp. 190; illustrated. 21s. net.)

put forward with the claim that "if the student knows what is contained herein, he may be considered grounded in the subject"; and the point of view from which they are written is defined by saying that they belong to "the older surgery," which is "based on a knowledge of pathology and anatomy . . . now being so replaced by the use of electric currents, radium emanations, and injections of all sorts." Now in almost all the subjects of which Mr. Rankin treats—for instance, cleft palate, undescended testicle, or club-feet—the newer school is not proposing recondite methods of treatment, but is accusing its seniors of neglecting to work out what they claim to be the foundations of their teaching—the relevant anatomy and pathology. The exact mechanism of the closure of the nasopharynx, the means of suspension of the testis, the true nature of the deformity so curiously described as talipes equino-varus—these are the points on which the older teaching on the surgery of childhood is being attacked. And for any definite statement on this groundwork Mr. Rankin's book may be searched in vain.

The book for all that is very interesting as showing the ways (not necessarily better ones) in which thought on the subjects treated is moving. One obvious contrast lies in the much greater severity of the measures recommended by the older school. In treating ordinary mastoiditis Mr. Rankin recommends making a hole large enough to put a finger easily through by "sacrificing the posterior three-quarters of the meatus." In talipes equino-varus the tendo Achillis is cut in those cases which come early for treatment, and astragalectomy or wedge-resection done in those which come later. In osteomyelitis wide removal of the shaft of the bone is advised, with the insertion of a glass rod to preserve length. Foreign bodies at the upper end of the oesophagus are removed by forceps guided by x rays, or, failing this, by a coin-catcher. Mr. Rankin dismisses hypospadias as intractable, without reference to the work of Edmonds on this subject; and for tonsillectomy uses the guillotine, which removes the organs attacked "sufficiently often."

As to anaesthetics, chloroform is of course recommended as the drug of choice, as ether takes too long to put a patient under, does not give relaxation nor freedom from movements, and runs all over the patient's face. If Scotland accuses the rest of the world of not knowing how to give chloroform, surely there is room for a little counter-criticism as to the local methods of giving ether which are suggested by this. No mention is made of intratracheal administration, nor of gas and oxygen, while it is doubtful if all of the newer school would agree that while the patient is "snoring loudly and regularly an ideal state of affairs is being maintained."

The photographs in the book, many of which come from the collection of that pioneer in this branch of surgery Mr. J. H. Nicoll, are extremely interesting and well reproduced. The drawings, on the other hand, at least one reader found unintelligible.

SANITARY SCIENCE

The second edition of Professor GERSCHENFELD'S *Bacteriology and Sanitary Science*³ consists in part of an ample statement of formulae for bacterial stains and culture media and a description of the methods employed for the preparation of antitoxins, antibacterial sera, biological tests utilized in diagnosis, allergic skin tests, and the like. But from these beginnings the author ranges widely over the fields of bacteriology, and discusses, in addition, the helminths and the arthropods, immunity and anaphylaxis, ventilation, the purification of water, the milk

supply, and the filterable viruses, to name only a selection of the contents of a copiously stocked volume.

It is rather curious to us, living on this side of the Atlantic, to observe that a book which deals so extensively with so medical a group of subjects should not be addressed to medical men, but should be intended for chemists, pharmacists, nurses, and other non-medical persons. Among the reasons given are that pharmacists sell biological products, that pharmacists more than medical practitioners are consulted by the public on questions of sanitation, and that pharmacists, and nurses also, having close contact with physicians and local authorities, ought to know enough of the above-mentioned topics, and others dealt with in the book, to be able to "converse intelligently regarding them." While we may perhaps permit ourselves to speculate whether these special topics, however ably presented by the author, are likely to be competently grasped by people not medically trained, we cannot, even if we would, deny the evidence of this second edition that there is in North America a section of the general public which, whether fully understanding or not, is at least interested.

For our own part we have read Professor Gerschenfeld's book with both interest and pleasure. We recommend it as a work of reference to medical officers of health in this country. In dealing with points which arise from time to time in the course of health administration they will find it of genuine service.

HEREDITY AND ENVIRONMENT

Professor LANCELOT HOGGEN has now published, under the title *Nature and Nurture*,⁴ the William Withering Memorial Lectures, which he delivered in the Faculty of Medicine of the University of Birmingham on a subject then described as "The Methods of Clinical Genetics." The original title was not a misnomer, and should attract medical readers, but that now adopted is the more appropriate as indicating the general subject under consideration. No teacher or serious student of genetics, or of subjects such as biology, physiology, medicine, or sociology (of which genetics forms an essential part), will fail to appreciate, on perusal, the learning, research, scientific acumen, and power of exposition which have gone to its making, or the importance of its methods and conclusions with regard to some of the most discussed medical and sociological problems of the day. Much of the book is not easy reading: concentration and logical appreciation are required of the reader throughout; but no one prepared to contribute these need be debarred should he be unable to follow in all their detail the algebraical expressions and calculations which are a necessary part of the author's complete exposition.

Professor Hogben demonstrates the all-pervading influence of environment in the formation or display of human characters or peculiarities, of the complexities of genetic constitution and methods of transmission, and of the relation of these influences on one another in the manifestation of the end-product. That what are to all intents and purposes the same end-products can be brought about in entirely different ways and by various combinations of contributing factors is clearly shown. The distinction in genetic inheritance between those differences which are recognizable in almost any environment in which the fertilized egg will develop and those manifested only within a fairly restricted range of environment is stressed and usefully illustrated by clinical examples from human disease or abnormality, both bodily and mental. The bearing of this on recent researches on mongolism is well brought out. After a chapter on the general medical

³ *Bacteriology and Sanitary Science*. By L. Gerschenfeld, Ph.M., B.Sc. Second edition, thoroughly revised. London: H. Kimpton, 1934. (Pp. 493; 55 figures, 5 plates. 21s. net.)

⁴ *Nature and Nurture*. By Lancelot Hogben, M.A., D.Sc. London: Williams and Norgate, Ltd. 1933. (Pp. 143. 6s. 6d. net.)

applications of genetic principles; the author studies in particular the principle of random mating, consanguineous parentage and the theory of inbreeding, and the genetic analysis of familial (as distinct from hereditary) diseases, and offers illuminating warnings as to the compilation and reading of pedigrees, which should be of great service both to doctors and to eugenicists. In this regard his three main points for the physician may be quoted:

"(1) If the physician is devoting himself to the study of a simple disease or a small group of diseases, he must treat all cases as if they had equal value for genetical purposes. It is just as important for the geneticist to know about the patient who has no affected relations as to know about the patient who can boast of a proud lineage of fellow sufferers.

"(2) If the physician obtains the family history of any isolated case of a rare familial disease he should place it on record whether there are affected sibs or not.

"(3) It is always important to give the age at death of both parents, the age of the mother at the birth of each of her offspring, the correct birth order of all sibs, including miscarriages, sex and age at death of all sibs, and age of onset of the disease of all affected members of a pedigree."

The author's development and illustration of these statements, and his reasons for making them, are of great interest; and it will be seen that he is not content with mere theoretical expositions of principles, however fundamental, but is concerned to be helpful in their practical application. The multiple character and varied modes of causation of mental defect are demonstrated, and it is pointed out that the division of diseases into two groups, mental due to heredity and bodily due to environment, is wholly unjustified, as is also the assumption that, when alternative explanations of the causation of a condition are possible, it must follow that an origin in heredity is the more likely. There is no occasion, says Professor Høegben, to magnify the importance of the genetic aspect of feeble-mindedness till it assumes menacing dimensions.

SPEECH DISORDERS AND SESQUIPEDALISM

Of recent years much attention has been paid in the United States of America to disorders of speech, particularly by educationists and psychologists. Some of the work done has been valuable. There is an American Society for the Study of Disorders of Speech. Its nomenclature committee has prepared a classification of the disabilities in reading which are closely associated with speech, and SARA M. STINCHFIELD, Ph.D. (Mrs. C. L. Hawk), in a book on *Speech Disorders*,⁵ whole-heartedly adopts this new nomenclature. Apart from the contents table and index, no fewer than six of the pages of her text are devoted to a bare list of these words and their synonyms, and it is stated that "as the entire classification will shortly be published elsewhere we shall confine ourselves to an abbreviated form for practical use in the speech clinic." These six pages of samples from the Dictionary of Terms make us fearful of what the entire classification may be like. Someone with a mischievous, almost impish, familiarity with a Greek lexicon, and a "crossword" expertness in juggling with letters and syllables, must have been at the disposal of the American committee, and given his patrons this amazing collection of polysyllabic words in full measure, pressed down and running over.

Mockery of the stutterm is unkind and sometimes dangerous. But if he were told that his trouble was known as "dysarthria syllabaris spasmodica," or alternatively "spasmophemia" (with twenty sub-varieties!), we think he would henceforward suffer from "aphemia pathemata—dumbness due to fright or passion (lalophobia)." Of the several causes of "dyslexia," difficulty in reading, "agnosia, due to unknown or uncertain

causes," comes first; the explanation would not be true of failure to read these pages in public. Next comes "amphidextotica, due to ambidexterity and the resulting lack of unilateral cerebral dominance." Ophthalmic surgeons have to use some big words, but despite their usual ambidexterity we think they would repudiate the ownership of this word. The author revels in sesquipedalian terms, and uses them with remarkable agility. But in the reader who has no more than a nodding acquaintance with them the book may induce a nodding which is neither a recognition nor an assent.

The first half of the book is taken up with speech disorders, though too much space is given to brain and cord diseases, which are better dealt with in a work on neurology. The second half is filled with the returns of "statistical studies of the speech defects of 3,000 college women and of public school groups." If well digested and well chosen some of these returns would be of interest, but prolixity smotherers them. Perhaps we may trace here the influence of the questionnaires which are so popular in the United States. One on "handedness index" is reprinted. There are no fewer than ninety questions, of which these are fair samples: "Which hand wraps the tie around when you tie your tie?" and "When standing with both feet together which foot goes forward first to catch yourself when you start to fall?" What was the fate of the centipede who tried to answer a like question?

THE EFFECTS OF ALCOHOL

An admirably simple, succinct, and informative account of the effects of the ingestion of alcohol is given in a small book entitled *Alcohol: Its Effects on Man*,⁶ by Dr. HAVEN EMERSON, professor of public health practice in the Columbia University and president of the American Public Health Association. The publisher's note does not err when it says: "In the present volume a noted authority on public health sets forth the facts clearly, frankly, and without propaganda; its findings constitute the most modern, sound, and accurate information available to-day." The only qualifications that might be added to this statement are that, for the sake of brevity and emphasis, the author's pronouncements have to be dogmatic, so that to some of them a proviso might be required if the book were intended for certain classes of scientific readers only; and that in the chapter on "Effects on Reproduction and Offspring" a too implicit reliance appears to have been placed upon the experiments of Stockard. In fact, since all but two of the United States require teaching with regard to alcohol to be given in every school in receipt of public money, the book is written "to provide school teachers and high-school and college students with the facts" relevant to this matter. It could scarcely be bettered for its purpose, for it has not only all the qualities already mentioned, but it is very interesting, well ordered, and well expressed. In this country, as in America, not only teachers and senior students, but most medical practitioners, will derive advantage from its perusal. The author not only quotes from the report of the British Medical Association's special committee on the subject, but he cites most apposite passages from the Book of Proverbs (chap. xxxi), and from Plato and Galen. It is impossible to forbear repeating a portion of Galen's:

"Does not wine act like a tyrant forbidding the mind to think as carefully as it did and to act as correctly as it did? . . . If it once gets into the body it prevents the steersman from handling the ship's rudder properly, and the soldier from keeping order in the ranks: it makes judges vacillate when they ought to be just, and presidents rule badly and impose unsound ordinances."

Notes on Books

Professor SAMSON WRIGHT'S *Applied Physiology* has had a well-deserved success since its first appearance in 1926. For the fifth edition, now published,¹ the text has once again been thoroughly overhauled, in order to keep it abreast with current developments of physiology. A certain amount of rearrangement of the material has also been carried out, and indications of these changes are given by the author in his preface. To make the book more useful to various classes of readers he has had printed in italics, in the table of contents, those parts of each subject which are wholly or mainly of clinical interest. In its revised form *Applied Physiology* will no doubt maintain the popularity it has already achieved among students and practitioners of medicine, while the needs of those working for an examination in "pure" physiology have not been overlooked.

The fact that a fourth edition of Dr. GEIKIE COBB'S *The Organs of Internal Secretion*² has been called for testifies to its continued popularity. Every chapter, with the exception of that on the endocrine glands and nervous disorders, has been revised, while chapters on obesity and on infantilism have been added. It is admittedly a book written by a practising physician for general practitioners, and the emphasis is laid on the clinical rather than on the experimental side. Perhaps a more definite account of pituitary basophilism might have been given, while we should have been glad to see reference made to hyperparathyroidism and to hypoglycaemia. The time has come when the part played by the cortex in Addison's disease might be more definitely accepted. Room for these topics could be made by condensing the chapter on nervous disorders, and restricting it to those more directly associated with endocrine disease. But it is a pleasantly written book and easy to read.

The thirty-third edition of the well-known *Handbook of Physiology*,³ with which the name of the late Professor W. D. Halliburton was so long and so honourably associated, has been very extensively revised by Professor R. J. S. McDOWALL, whose name appears on the cover as joint author. Among the more salient alterations are the use of bold type for terms and figures which should be memorized by the student; the omission of much of the detail of the connective tissues and elementary electrical apparatus, or its insertion in abbreviated form in the sections where this is appropriate; and the provision of original illustrations and an enlarged index consequent on the insertion of new letterpress rendered necessary by the steadily continuing advances in knowledge. In this way the book has shrunk a little in size; its usefulness has been greatly enhanced by the rearranging of the chapters, and the planning of the approach to the subject on a physiological rather than on the now obsolete anatomical basis. In a prefatory note by the publishers the history of this student's classic is traced from the first edition in 1848 under the authorship of William Senhouse Kirkes. In 1860 Sir William Savory's name was associated with that of Kirkes. Successive editions reflected the changing outlook of physiology, until in 1896 the book entered a new phase of still greater progress under Professor Halliburton's guidance. The many new features in the thirty-third edition will be welcomed by students, whose present-day requirements are always kept in mind.

The *Transactions*⁴ of the Tuberculosis Society of Scotland during the year 1932-3 have now been published under the editorial direction of Dr. FERGUS HEWAT of Edinburgh. The subjects dealt with include the detection

of tubercle bacilli in the blood stream in pulmonary tuberculosis; tuberculous disease of the middle ear and mastoid; phrenic evulsion; problems of research in tuberculosis; silica in relation to pulmonary disease; and the treatment of tuberculosis in relation to eye disease. The volume also contains notes of demonstrations before the society, a report on tuberculosis work in the United States, and some shorter papers and notes.

Tabulae Biologicae Periodicae,⁵ vol. iii, Nos. 2 and 3, provide a wide variety of biochemical data. One of the longest articles deals with the toxicology of poison gases. Another very useful series of tables summarizes present knowledge about the respiration of living cells. Further articles deal with the biochemistry of vitamins, oestrin, snake poisons, and other animal poisons.

Dr. LOUIS CAILLON of Vichy has written a good little book on diabetes,⁶ indeed the most practical and useful of its size that we know in French. All the necessary instructions about diet, injections, and urine tests are clearly detailed. As one might expect, much more attention is given to the spa treatment by water and baths than we find in English books, but the limitations of hydrotherapy in severe cases are frankly admitted.

Preparations and Appliances

AN OPHTHALMIC RULE

The ocular base line must be measured for every eye patient. The ophthalmic surgeon needs to measure it before proceeding to certain detailed subjective investigations—for example, binocular balance by means of the diaphragm test. The dispensing optician must measure it to determine the fit of spectacle frames and the centring of lenses.

In 1910 I showed to the Ophthalmological Society a form of callipers, or rule, whereby this measurement could be made with accuracy and speed. This rule has been much used. A new pattern has now been made by Messrs. Hamblin which is a material improvement. In the first pattern the moving member or cursor slid on the rule, so that a little dirt checked its free movement, and the wires by which the sighting is made were long and easily bent. In the new model the position of the cursor has been reversed; it now slides within the channelled frame of the rule. These channels give wide bearings with free, yet steady, movement to the cursor, and the interior housing gives protection to the wires. The new

rule is made of duralumin stampings, so that each rule is mathematically exact. It weighs only half an ounce, yet it is so strong that it may be carried in the pocket. The wires are of fine steel, wedged into the cursor by taper pins. The rule is black, with the millimeter scale engraved and filled in with white. There is a full range of 45 to 80 mm. The scale has a sharply bevelled edge so as to obviate parallax between the scale and the wire.

In use the rule should be held in the right hand with the root of the little finger crooked into the notch on the end of the handle; the thumb falls naturally into place on the little thumb-piece at the lower edge of the rule and which is part of the cursor. The patient looks at a light in the distance, and the observer sights with his own left eye the wire of the rule against the spot of light on the patient's right eye, and with his own right eye sights the other wire over the spot of light on the patient's left eye. For near vision the patient fixes a near point, and the distance between the corneal images of the light is taken as before.

The rule is obtainable from the manufacturers, Messrs. Theodore Hamblin, Ltd., Dispensing Opticians, 15, Wigmore Street, London, W.1.

MEDICAL RESEARCH COUNCIL

ANNUAL REPORT FOR 1932-3*

(Concluded from page 543)

WORK ON THE ANAEMIAS

The success that has during recent years attended research on the anaemias is a striking illustration of the great advantage that comes from combined laboratory and clinical work. Pernicious anaemia, formerly a fatal and incurable disease, has been brought under control, and the knowledge that has been gained by research into this disease has thrown much light on the physiology of normal blood formation—another example of the kind of contribution medical science can make to the "pure" science of physiology. As the report states:

"We know now that different forms of anaemia in man are cured by different substances, and we deduce from this that the performance of different stages in the formation of haemoglobin and of red blood cells is dependent on the presence of specific chemical factors, including iron, copper, a water-soluble substance in liver, an enzyme in gastric juice which seems to act with an 'extrinsic' factor in meat and yeast, and probably a part of the vitamin B complex. The discovery of these substances essential for the proper supply of haemoglobin in normal corpuscles has, as can be imagined, already greatly increased our knowledge and our appreciation of the significance both of different forms of anaemia and of the processes involved in their production. It is probable, for instance, that the liver active principle causes the conversion of the mother cells (megakaryoblasts) present in bone marrow into the daughter nucleated cells (normoblasts), and that iron and copper are necessary for the actual manufacture of haemoglobin and the conversion of the nucleated red cell into the granddaughter cell, the ordinary non-nucleated form. The enzyme haemopoietin in gastric juice (present in desiccated pig's stomach, but not in that of ox or sheep) cures pernicious anaemia by acting on meat in the food; it then produces a substance, possibly identical with the liver active principle, that converts the megakaryoblast of bone marrow into the normoblast. Thus it is probable that at every stage in the life of the red blood corpuscle a particular chemical agent acts as a stimulant; and that if this agent be absent the development process breaks down, with the production of a particular form of anaemia. Treatment consists in artificially supplying the missing factor."

Since the original discoveries of the American workers—Whipple, Minot, and Murphy—valuable contributions to the subject of anaemia have been made by English physicians. Dr. Helen Mackay has drawn attention to the incidence of anaemia in children; Professor L. G. Parsons has helped to unravel the difficult question of nutritional anaemia in children; Dr. L. J. Witts has advanced knowledge on the macrocytic and microcytic anaemias; Dr. J. F. Wilkinson has demonstrated the presence of an enzyme (haemopoietin) in the desiccated stomach of pigs and carnivora which cures pernicious anaemia; while Professor L. S. P. Davidson has also promoted research into the treatment of this disease.

CARDIOVASCULAR DISEASE

A most important investigation into chronic heart disease has been carried out in Sir Thomas Lewis's department by Dr. R. T. Grant. The basis of this work was a follow-up inquiry into a large group of patients with heart disease who had been under the observation of Sir Thomas Lewis and his colleagues in military hospitals during the war. Hitherto prognosis in heart disease, in the absence of a systematic survey of a large number of cases over a long period of time, has depended mainly on individual clinical experience. In Dr. Grant's investigation a thousand men with definite evidence of

acquired cardiovascular disease (chiefly of the valves of the heart) were observed for a period of ten years. At the end of this period fully half of these patients were alive, and approximately four-fifths of these "have lived uneventfully and comfortably." The inquiry has shown that the outlook for patients with valve defects is less serious than has been generally thought, and that the most important findings on which prognosis should be based are cardiac enlargement and cardiac failure. The type of valve lesion is of little significance, and, while prognosis is least favourable in aortic stenosis and syphilitic aortic regurgitation, there is no material difference in the death rates among those suffering from non-syphilitic aortic regurgitation and mitral stenosis. The average life of patients with aortic aneurysm is over five years. In syphilitic aortic regurgitation, without aneurysm, only 58 per cent. of patients die within ten years.

Other important clinical researches have been carried out at University College. Sir Thomas Lewis has for a number of years been making observations on coarctation of the aorta. He has shown that the blood pressure in the upper limbs is greatly and continuously raised; and from the fact that cardiac enlargement and failure are not greatly in evidence in cases of coarctation, he makes the point that the common association of raised blood pressure with enlargement and failure of the heart is not a simple question of cause and effect.

Sir Thomas is also engaged in investigating the syndrome known as erythromelalgia, in which there is redness and burning pain of the skin of the extremities. Dr. Pickering and Dr. Hess have been working on the headache produced by histamine. They have shown that headache provoked in this way does not arise in the scalp, and that it depends upon an intact sensory root of the trigeminal nerve. The effect of histamine is to bring about a fall of blood pressure and an increase of lumbar and intracranial pressures, as a result of cerebral vaso-dilatation, and the headache appears, not during these changes, but directly after they subside. It is suggested that the pain is caused by a mechanical disturbance related to the action of histamine on the vessels, and that the pain originates in the dura mater. Dr. Wayne, in an investigation into the angina of effort, has found that the amount of exercise necessary to produce pain in any one individual is, under standardized conditions, almost constant. He has also shown that the appearance and disappearance of the pain is not closely determined by the frequency of the heart beat. This is consistent with the view that anginal pain is caused by a relative myocardial ischaemia, and manifests itself when the energy expenditure of the heart rises above a certain level.

RESEARCH IN THE SPECIAL SENSES

The report states that during the past year the Council has been able to provide for intensive research into the physiology of the special senses. Some years ago it appointed a committee on the physiology of vision, and more recently a similar committee on hearing has been set up. Dr. C. S. Hallpike has a grant for whole-time work at the Middlesex Hospital, where he is investigating the electrical changes in the cochlea and the auditory nerve as they affect, or are affected by, the functions of different structures of the ear:

"It is through development in the physical aspect of research on hearing, when advance gained in physiological knowledge can be applied to principles of instrumental design, that the prescription of hearing aids may be expected to emerge from the empirical stage."

The Council has joined with University College in establishing the post of Reader in Special Senses, to be held

* Cmd. 4503. London: H.M. Stationery Office. 1934. (2s. 6d. net.)

there by Dr. R. J. Lythgoe, who has for some time been an active worker for the Committee on Vision. Four of the recent reports of this committee have dealt with the problem of colour vision, and it appears that defects in colour vision are commoner than was thought. About 4 per cent. of individuals in an unselected male population were found to be either red-blind or green-blind. More common than this type of colour-blindness is that in which there is sensitivity to all three primary colours, which are, however, seen differently from normal people. Persons in this group, while able to distinguish colours satisfactorily in ordinary circumstances, are liable to break down under unfavourable conditions. It was found that a number of men had passed the usual tests for entrance to the Navy, but had dangerously defective colour vision. As a result of this investigation more rigorous tests have been introduced.

THERAPEUTICS

The report includes a brief review of developments in the radium beam therapy of cancer, in which the affected part is exposed to massive irradiation from a large quantity of radium, held in a container, external to the body. Several grams of radium have been loaned for this purpose by the Union Minière du Haut Katanga, and responsibility for its safety and control has been undertaken jointly by the Council and the Department of Scientific and Industrial Research.

A number of new remedies have been tried out under the supervision of the Therapeutic Trials Committee. At University College Dr. E. J. Wayne has investigated the therapeutic properties of digoxin and digitalinum verum (Burroughs Wellcome and Co.). These two glucosides of digitalis, he has shown, are useful in the rapid treatment of heart failure with auricular fibrillation. Digoxin appears to be of particular value. It can be given intravenously or by mouth, and produces an effect within a few hours. Dr. J. Chassar Moir, at the same hospital, has found that ergotoxine ethanesulphonate (Burroughs Wellcome and Co.) is as effective as ergotamine in causing contraction of the post-partum uterus. Dr. J. M. H. Campbell, Dr. W. Evans, and Dr. J. C. Bramwell are examining the value of hormol derivatives (Boots Pure Drug Co. Ltd.) in the treatment of angina pectoris. It is pointed out in the report that, where the committee has failed to substantiate the therapeutic claims of any product, the manufacturers have agreed not to advertise these claims.

A number of new chemical compounds for the treatment of tropical disease have been tried out. Various workers have been investigating the trypanocidal properties of different drugs, and it has been found that the cure of trypanosome infection in rabbits by styryl compounds is followed by a long period of immunity to reinfection. Further tests have also been made of the effects of plasmoquine and atebirin on malaria.

SURGERY, OBSTETRICS, AND GYNAECOLOGY

At St. Mark's Hospital Mr. W. B. Gabriel and Dr. Cuthbert Dukes are carrying out an inquiry into the after-histories of patients with cancer of the rectum treated by operation alone or with radium. Follow-up records have confirmed the bad prognosis for those cases in which metastases are found in the regional lymph nodes at operation, and an attempt is now being made "to correlate the proved extent of the upward lymphatic spread of columnar-celled cancer of the rectum with the length of subsequent survival." Mr. Lambert Rogers has done further work on the surgery of the sympathetic nervous system. Regeneration of sympathetic nerves after

injury and alterations in blood supply following operation on these nerves are subjects of study.

At the Royal Maternity and Women's Hospital, Glasgow, Dr. Dugald Baird has continued his investigations on infections of the urinary tract in pregnant women. It has been found that invasion of the blood stream by *B. coli* is commoner than was thought, and that many cases of supposed pyelitis of the puerperium are in reality cases of *B. coli* septicaemia. Dr. D. F. Anderson, at the same hospital, has been unable to confirm the theory that diminution of the calcium content of the cerebrospinal fluid is associated with eclamptic convulsions. Dr. Leonard Colebrook and his co-workers have pursued their researches into the relation of streptococci to puerperal fever.

MEDICAL SICKNESS, ANNUITY AND LIFE ASSURANCE SOCIETY

At the annual general meeting of the Medical Sickness, Annuity and Life Assurance Society, Ltd., Dr. F. C. Martley, chairman of directors, in moving the adoption of the annual report, said that there had been a gratifying increase in the business during the year. A considerable part of this large increase was due to the initiation of the pension and insurance scheme for British Medical Association members and insurance practitioners. This had been given wide publicity, and the resulting business was very gratifying. The ordinary business was showing a satisfactory expansion, and the number of new entrants was increasing. The rapid increase in the "life" business during the last few years had now brought the "life" fund to approximately the same amount as the "sickness" fund. Claims on the life business had also increased, and in two or three instances the claims were concerned with comparatively young men, who had been wise enough to make provision for their dependants, but the mortality was well within actuarial expectation. As for the sickness fund, the influenza epidemic during the early part of 1933 was the severest in the experience of the society, and the amount paid away for that cause alone was in the neighbourhood of £6,000. With each fresh year the members holding the policies, and having had some experience of them, took the opportunity of increasing their cover.

Turning to the practice purchase scheme, Dr. Martley said that a large portion of the time of the officials was now devoted to interviewing and giving advice in this matter. There was a growing feeling of perturbation in the mind of many leading members of the profession with regard to the onerous terms imposed in some quarters on doctors who required capital for the purchase of practices. The terms offered by the society were as good as any that could be obtained, and better than many. This was because there was a board of medical men with full knowledge of the difficulties of the new practitioner. He also reported progress regarding the house purchase scheme and other sides of the society's business, and concluded with a reference to the recent jubilee and a tribute to the manager, Mr. Bertram Sutton, and the staff.

The report having been adopted, Dr. de Bec Turle proposed and Sir William Willcox seconded the re-election of the two directors who retired by rotation—namely, Dr. Martley, and Mr. R. J. McNeill Love. The chairman then brought forward a recommendation that an interim bonus be paid on all with-profit policies for permanent sickness and accident insurance and life assurance becoming claims during the present year. The recommendation was carried, and the meeting concluded with an expression of thanks to the chairman.

The annual meeting of the Franco-Ibero-American Latin Union, commonly known as the Umfia, was held in Paris on February 2nd, when the president and founder, Dr. Dartigues, surveyed the history of the Union, which was founded in 1920, and numbered 3,000 members belonging to thirty nations and speaking five languages (French, Italian, Spanish, Portuguese, and Rumanian).

British Medical Journal

SATURDAY, APRIL 7th, 1934

THE METHOD OF MEDICAL CARE

What in this country is commonly called "medico-sociology" seems to be more often spoken of in the United States of America as "medical economics," and the provision of a "general medical service for the nation" is regarded from the point of view of the "cost of medical care." In American discussions, too, there are those who appear to be unable to distinguish sociology from socialism. Such things are important, for, in commenting on those discussions, we have constantly to remind ourselves that not only may the exact connotations of words differ, but the angle of consideration may vary, and the circumstances of the country may not be identical with those that prevail in Great Britain. Moreover, it is easier to get provoked and angry about a political creed than about a science. Nevertheless, an attempt should be made on both sides of the Atlantic Ocean to understand and not to misrepresent what experience can contribute to the solution of common, or of similar, problems. It is with a wish to be helpful rather than provocative that we comment upon a meeting recently held in Philadelphia to consider the relationship of the physician (using the word in its American sense) and the community, as reported in the *Journal of the American Medical Association* for March 3rd last.

The report leaves the impression that the atmosphere of the meeting was too highly charged with personal antagonisms for the calm elucidation of the truth, and it may not quite convey in just proportion what was said by the various speakers; but the broad situation seems clear. On the one hand, there is a powerful body of persons who are conducting with no little success a campaign throughout the United States in favour of an extensive reorganization of the methods by which medical provision is made for members of the public who are unable to provide the full cost themselves, mainly by some sort of insurance scheme. These persons, though united as to the urgency of the need for such a change, are not necessarily of one mind as to the details of the scheme they would prefer, nor do they all seem able to make clear the exact nature of the arrangements they wish to establish. Over against this body of opinion stands the American Medical Association—or perhaps it would be more correct to say a number of those who at present officially voice what that Association is supposed to think—whose statements can only be interpreted as meaning that they are opposed to accepting any serious change at all. The latter attitude is surely unreasonable, for it can scarcely be denied that it is the duty of a modern civilized community to make provision for the health of its members if they cannot secure it for

themselves, or that in America as elsewhere there are large numbers who suffer from this disability.

The statements made in support of the position of the American Medical Association are that the changes proposed are socialistic, and therefore, it is implied, objectionable; that the present state of affairs is reasonably satisfactory, or at least will shortly become so by the action of the medical profession itself; and that experience of national health insurance in Great Britain and elsewhere has proved it to be a failure and detrimental to the interests of both profession and public. It is a curious comment on the first of these statements that in this country the provision of medical advice and treatment through a scheme of compulsory contributory insurance is generally regarded as a bulwark against the really socialistic movement to provide it by means of a whole-time salaried service. If the second statement were correct it is evident that the suggestions for change could make no headway, or that the medical profession ought to be in process of showing that such deficiencies as had been proved to exist were being actually supplied by practical steps taken under its own auspices. It is with the last statement, however, that we are most concerned, for it shows either ignorance of facts or a complete misapprehension of the situation in Great Britain. There are official resolutions of the British Medical Association and of the Conference of Panel Committees, almost unanimously adopted and from time to time reiterated, to the effect that the measure of success which has attended the experiment of providing medical benefit under the national health insurance system has been sufficient for the profession to unite in securing its continuance and improvement; that medical benefit under this system should be extended to include the dependants of all persons insured thereunder; that Poor Law domiciliary attendance should be merged in the insurance scheme; and that "immense gains" have accrued to the community by the establishment of the Insurance Medical Service. Neither the contrary opinion of certain individuals, nor the existence of defects within the service, nor the admitted possibility of some tendencies which would become dangerous if allowed to prevail, can stand against these emphatic official pronouncements. It is unwarrantable to portray collective medical opinion in this country as being other than that indicated; and it is unreasonable to demand as a proof of success that an immediate and consequential lowering of the mortality and morbidity rates of the country should be demonstrated. This illogical requirement was, in fact, actually laid down by one of the chief speakers at the Philadelphia meeting; but, for reasons which it would be easy to state did space allow but which must be fairly obvious, this is a condition impossible of fulfilment, at least for many years to come.

A much wiser attitude for the organized medical profession to adopt would be to admit that the need for further provision along the suggested lines exists, and to advocate means being taken to supply it; to

lay down at once certain fundamental conditions which must be fulfilled if the good will and co-operation of the profession is to be secured, and certain other arrangements, not so fundamental, which it is highly desirable to make to this end; and to examine and influence any proposed schemes so as to bring them into accord with the conditions and arrangements so laid down. In such a work as this the experience of Great Britain and of some other European countries must be of real value. The points which general medical opinion in this country would undoubtedly emphasize are that the scheme for the provision of medical advice and treatment should be separated as completely as possible from insurance provision for cash payments of any kind to insured persons; that from the beginning provision for a full medical service, and not merely for a general practitioner service, should be made; that the right of all medical practitioners to be members of the service should be secured; that there should be no interference between doctor and patient when once this relationship has been brought about; that there should be a close and appropriate part taken by the profession itself in administration; and that this administration should be through topographical organizations and not through a multiplicity of "approved societies." Some of these conditions exist in the English service and have proved their immense and essential value; the absence of others has been the cause of most of the difficulties we have experienced. To obtain all of them may require great effort on the part of the American Medical Association; but, with them, there need be no apprehension of disaster to the profession or disadvantage to the public. Experience points to a contrary conclusion. In the pamphlets published by the British Medical Association, entitled "A General Medical Service for the Nation" and "The Essentials of a General Medical Service," will be found an ampler exposition of these important features and requirements.

RADIODIAGNOSIS IN CLINICAL MEDICINE

The discovery by Röntgen of the rays which, because of their mysterious properties, he named x rays gave to science a new method of investigating animate and inanimate bodies. Their use has extended into many departments of science, but their application to medicine has probably been the most fruitful of all. Röntgen himself introduced the methods of radioscopy and the registration of the images on photographic plates. The study of the skeleton and search for foreign bodies were the first steps in employing the new rays in medical science. This early radiodiagnosis was soon followed by exploration of other fields. Already in 1896, a year after Röntgen's discovery, Bouchard applied the new technique in studying the natural transparency of the lungs compared with the shadow of the heart and skeleton, pointing out that by the information gained the physician was likely to benefit

by the new method as well as the surgeon. A further step led to the use of artificial contrast materials: opaque meals of bismuth and barium for the digestive tract; lipiodol in the spinal theca, in the uterus and Fallopian tubes, and in the bronchi; opaque dyes for demonstrating the gall-bladder and renal tract. And probably the list is not yet closed of methods which have made such development in the domain of diagnosis alone, apart from the application of the x rays to treatment.

The field has become so wide that a special branch of medical practice has arisen, practitioners devoting their whole time to x -ray work after special study and often an additional diploma. This specialism has grown up not so much on account of the technical problems of management of the complicated apparatus used, as of the need for training in the accurate interpretation of the resulting pictures. Each of us would feel competent to express an opinion on the faithfulness of an ordinary photograph of a scene or person, but in the case of the x -ray photograph we are dealing with shadows of a three-dimensional world imposed on a two-dimensional plane. As Bécélère says, "the x rays are never mistaken. It is we who make the mistake of demanding from them more than they can give or of interpreting their language wrongly." Knowledge not of anatomy and pathology alone is required but also of the normal and abnormal appearances, the shades and degrees of which can only be assessed by constant practice. Often, indeed, "the difference is too nice, where ends the virtue and begins the vice." So that it is necessary to control the interpretation offered by taking into account the data furnished in the history of the patient's illness, the clinical examination, and ancillary laboratory tests, chemical and bacteriological. For this it is not enough to receive a report from the radiographer's darkroom. The actual pictures of the lesion should be submitted for discussion between the practitioner in charge of the case and the radiologist. In many cases it is advisable, in some cases necessary, for the clinician to be present himself at the x -ray examination. That is to say, the practitioner attending the patient must be not only a clinician of experience, but must have some knowledge of radiodiagnosis.

The knowledge needed for this purpose may be obtained by discussion and oral teaching, but that there is scope and demand for instruction from books is shown by the appearance in the different civilized countries of the world of textbooks and manuals devoted to various aspects of radiological practice. Some of these are for the specialist, some are written by specialists to instruct and enlighten the clinicians. One of the most recent and most satisfactory of the latter class is a manual of radiodiagnosis¹ by Dr. Ledoux-Lebard, head of the radiological clinic in the Paris Faculty of Medicine. In two handy volumes Dr. Ledoux-Lebard has brought together the essentials of the subject, which he has divided into eight sections

¹ *Manuel de Radiodiagnostic Clinique*. Par R. Ledoux-Lebard. Deux volumes. Paris: Masson et Cie. (200 fr.)

or "books." The chapter headings and a good index enable the practitioner with a working knowledge of French to turn quickly to any subject on which he needs information and guidance. These subjects are adequately described and fully illustrated; special care has been given to the illustrations, both of typical lesions and of the common variations. With such a manual for reference and study, the clinician will be able to appreciate the finer points in the interpretation of modern radiograms. The books on similar lines which have been published in the English language are usually in the nature of atlases of radiograms, or large volumes on special subjects. In the former there tends to be inadequate discussion of the diagnostic points, while the latter class appeals to the specialist rather than to the busy practitioner. A translation of Dr. Ledoux-Lebard's book with editing of some parts to meet the constant advances of radiological work would probably be welcomed.

THE MASTER GLAND

The manifold functions of the pituitary gland increase in numbers as enthusiastic research proceeds. The long neglect of this organ seems to be more than compensated for by the extraordinary importance it now assumes in endocrinological research. It seems to be well established that the anterior lobe has an important effect upon growth and sex development. The attribution of these activities to this gland is accompanied usually by physico-chemical evidence of "hormones." Houssay's demonstration of a diabetogenic hormone in the pituitary is based on most convincing evidence, although it was long ignored by other workers in the field of carbohydrate metabolism. This work showed that in the absence of the pituitary gland pancreatectomy did not produce the typical picture of diabetes. More recently Anselmino and his co-workers at Düsseldorf in a series of papers claim to have demonstrated a further series of "tropisms," which must be associated with the pituitary gland. By simple drying of fresh anterior lobes with acetone and extraction with distilled water, a filtrate is obtained which is buffered at pH 5.2 and ultrafiltered. The ultrafiltrate is injected into male rats for some three or four days. Since the gonadotropic and thyrotropic fractions from the pituitary are not ultrafilterable, the Anselmino principle is distinct from these. The result of injection of the latter into the rats was to produce a new growth of islets of Langerhans and an increase in size of those already present. Since presumably such an extract would indirectly give rise to insulin-like effects, Anselmino proceeded to show that it lowers the blood sugar of dogs, that it depresses adrenaline hyperglycaemia, but that it has no effect on the blood sugar if the pancreas is removed. Thus it appears that the pituitary produces both an insulin-stimulating and an insulin-antagonizing hormone. Continuing on similar lines in regard to the influence of the pituitary on other glands, Anselmino and his colleagues found that extracts could be prepared which, injected into rats, resulted in a marked enlargement of the parathyroid glands, with increase in the clear faintly staining

principal cells, decrease in the more deeply staining cells, and absence of oxyphil cells. Further investigation revealed that these extracts increased the serum calcium of rats and dogs, but failed to do so if the parathyroids were extirpated. Thus it seems that the pituitary elaborates a parathyroid-tropic hormone. The next step in Anselmino's researches¹ was the demonstration in the infantile female mouse (castrated) of an enlargement of the adrenal cortex after injection of a pituitary extract which differed in properties from all hitherto known extracts except the pancreatropic one he had previously described. The histological evidence given in his most recent paper seems satisfactory, and shows that the increase in size of the adrenal cortex is principally restricted to the zona fasciculata and the zona glomerulosa. This work is the more impressive since Collip and his co-workers had previously found that the atrophy of the adrenal cortex which follows hypophysectomy can be prevented by injections of pituitary extracts containing what Collip calls the adrenotropic hormone. The position thus seems to be that the anterior pituitary gland exerts a controlling influence on the whole endocrine system; this is not only in regard to the secretory activity of the already existing gland tissue, but it can stimulate an increased growth of such tissue. It looks almost as though the pituitary had now established its right to be called the master gland.

CARBOHYDRATE METABOLISM AND LIVER FUNCTION

In a recent article Mollerstrom² attempts to explain the daily variations in the blood sugar in diabetes by relating them to a periodic rhythm of liver activity both in carbohydrate and in biliary function. It has been known for many years that when some diabetics are given three or four equal meals in the day the most likely to produce glycosuria and hyperglycaemia is breakfast. Mollerstrom has convincingly confirmed this fact and has adduced for the first time a reasonable explanation founded on experimental work by Forsgren. The latter found a twenty-four-hourly periodicity in which glycogen and bile salt production alternate. The glycogen content of the liver is highest from about 3 a.m. to 11 a.m. and rapidly decreases after this, largely independent of food, while the bile acid content simultaneously increases and reaches its maximum in the evening. Thus an inherent rhythm of high glycogen and low bile acid production alternates in the liver. These facts seem to be clearly proven, and not only adequately explain why breakfast alone may produce glycosuria in diabetics, but why, in the insulin case, there is such a marked tendency to hyperglycaemia from 7 a.m. to 11 a.m. The author suggests that a far better effect can be obtained by giving insulin much earlier than usual in the morning—say, at 5 or 6 a.m.—instead of only half an hour before breakfast. In most cases, however, such a suggestion cannot be carried out without great practical inconvenience, and fortunately makes little difference to the welfare of the insulin case. It is difficult to agree that such a rhythm should be considered in practice, instead of the more humane considerations of usual habit. The author

¹ *Klin. Woch.*, February 10th, 1934, p. 209.

² *Arch. Int. Med.*, November, 1933, p. 649.

does not discuss the importance of this endogenous glycogen rhythm on the still disputed theories of the origin of glycogen. Is it immediately laid down from ingested carbohydrate or mainly formed by endogenous production by the liver? The author's paper naturally shows the importance of the latter origin, but does not disprove the former. The problem of glycogen formation in the liver remains unsolved, but every fresh fact contributed emphasizes the importance of this mysterious substance in the nutritional supply of blood sugar.

THE CANNING OF FOOD

The preservation of food by canning received its first impulse in 1795, when Napoleon Bonaparte inspired the French Government to offer a prize for a new method of preserving food. The original containers were made of glass. The substitution for these fragile vessels of the more durable "tin can" was the happy thought of an Englishman. The earliest developments on a large scale took place in North America, where also later the researches of Prescott and Underwood into time and temperature conditions ushered in the era of scientific canning. In 1929 one hundred thousand workers were employed in the United States turning out a matter of 10,000 million cans of preserved food. Compared with these figures the dimensions of the industry in Britain are comparatively small, though the country consumes large quantities of imported canned goods. In a recent paper on canning Mr. T. N. Morris describes the process as carried on to-day, and deals with some technical problems of the industry: The tin plate of which the cans are made is mild steel covered with a coating of tin. This coating is extremely tenuous, less than one ten-thousandth of an inch in thickness. It is in consequence slightly porous and probably also suffers some stripping at bends when the cans are being made up or closed. In this way steel is left bare, and when an acid fruit is put into the can an electro-chemical reaction ensues between the two metals. At first the steel forms the corroding anode and the tin the non-corroding cathode; but soon these relations are reversed, and finally a static condition is established as a result of which acid fruits in cans often keep for years in good condition. Lacquering is largely employed by manufacturers in order to check corrosion of this kind and the subsequent impregnation of the food with tin or iron. Lacquer is an alcoholic solution of the resinous substance shellac, and with perfect lacquering, as the paper points out, protection of the food from the metals would be complete; but imperfect lacquering not only fails, it may even aggravate the condition it is intended to remedy. Too thin a lacquer does not close the pores in the tin coating. Thus the steel beneath is still left exposed, and the greater the area of steel to tin the more intense the electro-chemical reaction and the corrosion which it entails. The hydrogen freed by the electro-chemical reaction distends the cans without bursting them; it diffuses through the steel plate, and may by its pressure raise blisters in the outer enamel of cans. Mr. Morris rightly claims for canned foods the merit of being easily handled. The cans are proof to the ordinary shocks of transport, and secure their contents against

rats, mice, marauding insects, and other pests. That canned foods are not always sterile, and do not indeed require to be sterile, has been demonstrated by the work of W. G. Savage and others. It would be quite easy for the manufacturer to produce an invariably sterile article, but the temperature and duration of exposure necessary for such a result would in many cases macerate the food, altering it out of resemblance to its natural self and rendering it unsaleable. On the other hand, if the heating process is insufficient to control any proteolytic bacteria present the food will undergo "spoilage"—that is to say, decomposition—and once more be unsaleable. So between Scylla and Charybdis the manufacturer has to steer a course which in the early days of canning may often have been disastrous, but which now, thanks to accumulated experience, leads to results which, with scarcely an exception, are satisfactory to all concerned. The primary purpose of the processing by heat is to prevent loss by spoilage, not, as is sometimes supposed, to destroy bacteria which might otherwise give the consumer food poisoning. Every care is taken to exclude such pathogenic organisms at the outset by using the purest raw material only, and later to debar them from access by scrupulous cleanliness at subsequent stages. There is no good foundation for the view that canned foods, as such, are more apt than other prepared foods to convey the germs of that disease condition which, even in otherwise well-informed circles, is often still most erroneously termed "ptomaine poisoning." The question of the vitamin content of canned foods is of some moment. The capacity of a vitamin in a food to withstand the heat of processing depends primarily on its general power of heat resistance. The thermostable vitamins may be expected to survive in the finished product. But even the vitamins which belong formally to the thermolabile class may show themselves capable of withstanding heat if heated in the absence of oxygen. This condition is one which may be said to be almost expressly furnished in the routine course of the canning process, for the producer, in order to prevent the development of the aerobic bacteria which originate spoilage, makes every effort to reduce the air in his cans to the vanishing-point. There would therefore appear to be warrant for the claim that, so far as vitamin content is concerned, canned foods in general are not significantly inferior to their fresh originals. On this showing the canned tomato, described as especially rich in vitamin C, is a reservoir of antiscorbutic virtues which can be usefully drawn upon during the lean seasons when fresh fruit and vegetables are hard to come by.

A SAFE MILK SUPPLY

The Minister of Health, Sir Hilton Young, and the Minister of Agriculture, Dr. Walter Elliot, received, on March 27th, a deputation of scientific workers arranged by the London School of Hygiene and Tropical Medicine, and consisting of Dr. J. A. Arkwright, Professor J. C. G. Ledingham, Dr. F. C. Minett, Professor H. Raistrick, Professor G. S. Wilson (chairman), and Dr. N. C. Wright. They were introduced by Sir Austen Chamberlain, chairman of the Court of Governors of

the School. The object of the deputation was to bring to the notice of the Government its views as to the desirability of ensuring a clean and safe milk supply for the country in general, with particular reference to the policy of the Government as announced by the Minister of Agriculture on February 22nd. The deputation urged a measure of compulsory efficient pasteurization of all liquid milk intended for human consumption, coupled with measures for the eradication of disease in cattle and the stimulation of clean milk production. A memorandum, embodying proposals for a policy which might receive the support of medical, veterinary, and agricultural interests, was put in. The Ministers, in reply to the points raised, said that these were under examination by the Cattle Diseases Committee of the Economic Advisory Council, and the report of the committee and the views of the deputation would receive careful consideration by the Government. The legislation about to be introduced would be in general terms, and would permit full consideration to be given at a later stage to the matters dealt with by the deputation.

ROYAL MEDICAL BENEVOLENT FUND

The annual general meeting of the Royal Medical Benevolent Fund took place on March 22nd, with Sir Thomas Barlow presiding. Reports were made to the meeting by Dr. L. G. Glover, the honorary treasurer, and Mr. R. M. Handfield-Jones, the honorary secretary, which showed that although last year a considerable number of new subscribers were enlisted, and the revenue from subscriptions and donations increased, reaching a total of £11,856, it was insufficient to meet the volume of applications for help which the committee could not resist. It is the income from this source, after a certain deduction has been made for working expenses, which provides the annual maintenance grants and the emergency and single grants, and under these headings the committee has been called upon to vote £12,582, with the result that the reserve fund has been drawn upon to the extent of £1,435. Unless a larger measure of support is forthcoming this year the committee will have to reduce its grants distribution by £1,700 as compared with last year's figure. As many as 606 applicants for grants had their cases sympathetically considered during the year, and in addition to its annual and occasional grantees, the Fund has 191 annuitants on its books. Taking the grants and annuities together, the amount distributed reached the record figure of £18,920, and this was done on an administrative and publicity expenditure well below 10 per cent. of the income. A number of pathetic cases were described to the meeting. One was that of a 75-year-old widow of a medical man, who has spent the last four years nursing her husband, and declares that, having worked all her life, as soon as she possibly can she will start again, but at present is too worn out to do anything—"four years of nursing takes it out of one." In this case a grant of £26 has been made to supplement the old-age pension, the rent of a cottage, and the sale of some personal belongings, which are her only sources of income. The daughter of a medical man, who has been similarly assisted, is a music teacher reduced to selling her violin to buy

food. Another lady, also the daughter of a medical man, has maintained herself as a letter carrier in a wild and scattered district of Scotland until she has become paralysed and bed-ridden. The legacies received during 1933 amounted to £4,823, a sum which has been transferred to capital account. The book value of the Fund's investments is £160,267; the income from these investments is almost wholly absorbed by the provision for the annuities. The largest sum paid in a single annuity is £100. Votes of thanks were passed at the meeting, first of all to the Ladies' Guild attached to the Fund (which itself makes relief and maintenance and educational grants amounting to more than £5,000 in the year), to the British Medical Association and its Charities Committee (which allotted £1,446 to the Fund during the year), to the Medical Insurance Agency (for help which has now extended over very many years), and to the editors of the medical journals (for much useful publicity). On the motion of Mr. Warren Low, seconded by Dr. R. O. Moon, Sir Thomas Barlow was re-elected president, Dr. Glover honorary treasurer, and Mr. Handfield-Jones honorary secretary. The names of Sir Ashley Mackintosh, Professor D. P. D. Wilkie, and Professor Archibald Young were added to the list of vice-presidents, on the motion of Dr. C. O. Hawthorne, seconded by Dr. Herbert Spencer.

SIR HENRY WELLCOME

The American Pharmaceutical Association has conferred its Remington medal for distinguished service to pharmacy upon Sir Henry Wellcome, LL.D., F.R.S., Hon. F.R.C.S., founder of the Wellcome Research Institution and head of Burroughs Wellcome and Co. Apart from the research and experimental laboratories of the business firm, Sir Henry Wellcome has established a number of scientific research laboratories and research museums which are co-ordinated under separate direction as the Wellcome Research Institution, whose fine new building in the Euston Road, London, has not yet been formally opened. We learn also that the President of the French Republic has recently conferred the honour of La Croix de Chevalier de la Légion d'Honneur upon Sir Henry Wellcome.

We publish in the *Supplement* this week the letter addressed to his fellow practitioners by Dr. H. Guy Dain, announcing his candidature for election to the General Medical Council to fill the vacancy among the direct representatives for England and Wales caused by the death of Dr. Christine Murrell.

We are asked to amend the notice of the programme for the Section of Surgery at the forthcoming Bournemouth Meeting, which appeared in the *Supplement* of March 31st (p. 122). The discussion on "Bad Surgical Risks," on Thursday, July 26th, will be opened by Mr. Gordon Taylor of London, followed by Professor A. H. Burgess of Manchester and Mr. Ernest Finch of Sheffield. On Friday there will also be a short paper by Mr. G. A. Mason entitled "Post-Operative Management of Cases of Acute Empyema Thoracis."

New Zealand

[FROM OUR CORRESPONDENT IN WELLINGTON]

Physicists and Radiotherapeutics

The New Zealand branch of the British Empire Cancer Campaign is impressed with the extreme variations in dosage and control of deep x-ray therapy machines and the varying and conflicting methods of radium and radon application. This subject was discussed at the Fourth Cancer Conference at Canberra in Australia last year, and is to be further considered at the conference in April. In the meanwhile, the physicist who has been in charge of the radon plant in Wellington has been engaged, with the assistance of a grant from the Travis Cancer Bequest, to act in an advisory capacity to the various cancer treatment centres in New Zealand. He has been sent to Australia for four months' research work, and will first study under Professor Laby, F.R.S., of Melbourne University, and Mr. Turner, physicist to the Commonwealth Government; later he will take a course of study at Sydney. Spectroscopic and other methods of measuring dosage will be studied and an attempt made to standardize and calibrate the plant used for this form of treatment at the various centres in New Zealand. At the Cancer Clinic in Wellington, during the past four years, various methods of radium and deep x-ray therapy have been applied, and the results have steadily improved. Still different methods have been used in Dunedin and Christchurch, and more uniformity is desired in the light of experience, greater accuracy and certainty of dosage, and greater protection for both patient and operator. The establishment of a course of study in radiology, perhaps at Melbourne, has been discussed; the course would be for surgeons who wish to qualify to treat cancer by combined surgical and radiological methods, and a diploma would be given. The impression is also strengthening that the services of a qualified physicist are necessary in all radiotherapeutic clinics.

Charge of Manslaughter Against a Nurse

A verdict of "Not guilty" was returned in a recent case in which a nurse, who was formerly matron of a public hospital in a small town in New Zealand, was charged with manslaughter, in that, being in charge of a patient, she did not take sufficient care, with the result that her alleged neglect led to the patient's death. The deceased, a maternity patient, died after an enema had been given by the accused, who was relieving the maternity nurse ordinarily in charge of the ward. It was found that the basin used in giving the enema had contained a solution of carbolic acid, left in a cupboard by the maternity nurse. The facts were not disputed, and no evidence was called for the defence. The counsel for the accused pleaded that the Crown had failed to prove culpable negligence. The accused had been under the impression that she was handling an innocent solution, and there was no reason why she should have expected it to be otherwise. The law required reasonable caution and care, not the utmost caution. The jury gave its verdict after thirty-five minutes' consideration.

To the Antarctic

The importance of a doctor in a Polar expedition was exemplified by the regrettable serious illness of the doctor with Admiral Byrd's expedition, and his return to New Zealand in the ship *Jacob Ruppert*. Admiral Byrd sent a wireless message to New Zealand intimating the illness and early return of the sick surgeon, and appealing for a doctor to serve at the expedition's base in Little America for at least a year. There was more than one

volunteer, and the services of a Nelson practitioner were accepted. It was at first arranged that the *Jacob Ruppert* should make a further voyage to the Antarctic with the relieving doctor on board, and that a plane from the expedition base should meet the ship at sea a considerable distance from the Bay of Whales. In the meantime, however, the research ship *Discovery II* arrived at Auckland, and proceeded to Port Chalmers to embark the doctor for the Antarctic. The other ship of the Byrd expedition, the old Arctic exploring ship now known by the name of the *Bear of Oakland*, will, if the ice permits at a suitable time, sail north to meet *Discovery II* to save the latter as much time as possible. On the voyage south the *Discovery II* will call at the Antipodes Islands to search for castaways. During the return trip from the ice barrier to New Zealand the captain of the *Jacob Ruppert* was taken ill with severe pneumonia, and his life was almost despaired of. The doctor on board, invalided from the Antarctic, devoted his attention to the captain, and his skilful treatment and devotion are highly praised by all on board, not least, of course, by the captain himself. Two facts emerge from a consideration of these arrangements; first, that wireless has bereft the Polar regions of silence and isolation; and, secondly, that, as in ancient times, a doctor should be honoured and cherished as being "worth many men."

England and Wales

Centenary of John Heysham of Carlisle

On March 23rd a special service was held in Carlisle Cathedral to celebrate the centenary of the death of Dr. John Heysham, founder of the Carlisle Dispensary and author of the Carlisle tables of mortality. This was followed by a meeting in the Crown and Mitre Hall, when Dr. C. M. Graham delivered a commemorative oration and the president of the Institute of Actuaries gave an address on the Carlisle mortality tables. Dr. Graham reviewed the life and surroundings of Heysham. After being educated in a school belonging to the Society of Friends he had been apprenticed to a surgeon in South Westmorland, and had combined with his work the study of bird life in the local dales and of sociology. During the latter part of his five years' apprenticeship he worked at Latin and mathematics, and then went to Edinburgh, where he qualified in 1777. In the following year he started practice in Carlisle, where his first activities seem to have been directed against the prevalent ignorance and superstition in matters of health and sickness. His passion for accurate information led him to realize at once that very little was known about the community as a whole, and he therefore set out to compile a statistical registration of births, deaths, marriages, prevalent diseases, and the effects of various local industries on the duration of life and the incidence of disease. Very early in this work it became apparent that important issues were emerging. From the beginning of 1779 to the end of 1787 he persevered, by which time his gifts as a statistician had become well known to the leading insurance societies throughout the kingdom, and eventually the Carlisle tables of mortality were accorded general acceptance. Their data were found to be more reliable than those of the Government, and they were adopted by all the leading countries of the world. One immediate effect was the incentive to investigate the causal conditions of the more serious infections. At that time typhus fever and small-pox were rife in Carlisle, and Dr. Heysham was soon able to incriminate the local badly constructed and ill-ventilated houses. Action followed, and this sanitary science pioneering quickly wrought great benefit. Meanwhile his

own practice extended rapidly until his dwelling proved quite inadequate to the demands on it. The Dean and Chapter of the Abbey provided a room for him above the Abbey Gate as an emergency measure, and a subscription list was opened. In 1782 Dr. Heysham was thus enabled to found the Carlisle Dispensary, and larger premises were later acquired in the Tithebarn, Heads Lane. In 1857 the present Dispensary building was established in Chapel Street. Dr. Graham remarked that at the inauguration of the Dispensary his great-grandfather had been associated as honorary physician with the founder. In addition to these labours, Dr. Heysham was a justice of the peace and a deputy lieutenant for the counties of Cumberland and Westmorland. He was very active politically under the Lowther Tory domination of the period, being an ardent partisan, but towards the end of his life his sympathies became Whig. He was intimately associated with the mayor and corporation. It is recorded of him that he never had a day's illness in the eighty-two years of his life.

Heysham's Contribution to Statistical Science

Mr. W. B. Elderton, president of the Institute of Actuaries, said that Dr. Heysham's new contribution to statistical research was his recording of the population and the mortality person by person and age by age, as no one previously had done. He produced a census in 1780, which was the first mortality table of the kind now taught to actuarial students; this was made possible by the accuracy of his statistics rendering possible intelligent interpretation. In 1875 about one-third of assurance offices were still using the Carlisle tables, and five were still employing them in 1880, although by that time more suitable tables had been evolved. The criticisms of them which led to their ultimate supersession had actually arisen from the following to their logical conclusions of the principles which Heysham had himself brought to light. Under the age of 30, he had set himself to counting the houses and inhabitants, tabulating his results, counting the deaths and setting out their causes age by age and person by person, recording influences likely to be causative, and then repeating the whole process in order to verify his deductions. Without such pioneer work it would have been impossible to frame the schemes of pensions and insurance which were so prominent to-day. Mr. T. G. Kyd, secretary to the Government Actuaries Department, compared Heysham's work with the pioneer achievements of Harvey in medicine. As a fitting conclusion, to the commemoration ceremony a fund was inaugurated to improve and modernize the Carlisle Dispensary, which still depended entirely on voluntary support. It was mentioned that at his death Heysham had left a sum of £1,000 to the Carlisle Corporation to endow a people's park and recreation centre. This has now reached the figure of nearly £2,800, and would be devoted to the provision of a Heysham Park in the Raffles area of the city. The work is now nearing completion.

The One-Pipe System of Drainage

A matter which has received considerable attention lately among surveyors, builders, and domestic engineers is the installation of the one-pipe system of drainage. This modern system, for suitable buildings, has been advocated by sanitary authorities and the professional associations concerned, but it does not comply with the present requirements of the L.C.C. by-laws. Accordingly, the Central Public Health Committee of the Council is proposing to amend the by-laws to permit of the installation, under conditions, of this system. In ordinary drainage the removal of excretal matters from water-closets, slop-sinks, and urinals is effected by a pipe connected

direct to the drain, while the removal of waste water from baths, lavatory basins, bidets, and sinks is carried out by means of a second pipe, separate from the other, discharging the waste water over or into a properly trapped gully connected to the drain. In the one-pipe system the pipes from all these outlets are connected direct to the drain by a single pipe, to which they are joined. The primary distinction between the two arrangements, therefore, is that in the one-pipe system drain air is in direct contact with the water content of the trapped outlets of all the connected fittings, while in the two-pipe system it is in direct contact only with the water content of the trapped outlets of fittings receiving excretal matters, as aerial separation between the drain and the waste pipe conveying waste water from baths and lavatory basins is secured by disconnecting the waste pipe at the point of discharge over or into the trapped gully. The one-pipe system is largely used in the United States, where it is said to be satisfactory in operation. It is considered that it can be made sanitariously efficient if deep-seal and otherwise suitable traps are used, and adequate trap ventilation provided. It is expected that the use of the one-pipe system will be, in the main, limited to large buildings such as hotels, where from the standpoint of unsightliness it is desired to limit the number of exposed pipes to the minimum. It will probably be installed in many hotels where the provision of lavatory basins in bedrooms is usual. The waste pipes of these fittings will connect direct and be in aerial communication with the drain, and, where the drain is not intercepted from the sewer, in aerial communication with the latter. It is thus essential that every possible precaution should be taken to ensure that the trap shall have an effectual water seal, and the requisite specifications are made in the new by-laws. Ventilating pipes are also to be required for all traps connected with the one-pipe system. The by-laws await a second meeting of the Council for their confirmation.

A Costs Scale of Minimum Needs

Sir Hilton Young, the Minister of Health, received a deputation on March 23rd from the Children's Minimum Organizing Committee. The deputation was introduced by Miss Rathbone, M.P., chairman of the committee, and included Sir Francis Acland, M.P., Mrs. Hubback, Miss Tuckwell, Mrs. Drake, Miss Shaw, Miss Phillips, Miss Hawtrey, Dr. Geffen, and Miss Green. It urged that a scale representing the cost of the minimum needs for the health of families and individuals should be determined, adjustable from time to time and from place to place according to variations in the cost of living, and should be used for the guidance of authorities in all forms of relief and assistance; that the existing discretionary powers of local authorities to provide milk for children under 5 and for expectant and nursing mothers should be made compulsory; and that the practice of rebates from rents of municipal houses, in respect of children or of income in proportion to the number of children, should be encouraged. The Minister, in reply, said he would first recall the deputation's attention to what the Prime Minister had said when receiving a similar deputation from the committee recently. Scales, though to be regarded with caution, served a useful purpose as a working guide to remove anomalies. The contemplated Unemployment Assistance Board would provide a machinery for dealing with the whole problem on a more adequate basis than had been possible in the past. He shared the committee's keen interest in the question of milk to children and mothers, and he was engaged, with the Departments concerned, in working out the best distribution of the considerable moneys which the Government had afforded for this purpose. Pressure, where necessary

in the ordinary course of administration, was to be preferred to turning the statutory power of local authorities into a general obligation. Local authorities had been given very elastic powers for relating rents to means, but he himself had almost no power of intervention.

Drinker Respirator at Great Ormond Street

By the generosity of the Imperial Chemical Industries the Hospital for Sick Children, Great Ormond Street, has been presented with a Drinker respirator, which was installed at the beginning of March. At a Press demonstration, held on March 14th, Mr. R. W. Gorman Davis of the firm of Siebe Gorman, and Dr. G. P. Crowden, lecturer on industrial science at the London School of Hygiene and Tropical Medicine, explained, with the aid of a cinematograph film, the working of the apparatus, while Dr. F. J. Poynton, senior physician to the hospital, described the steps by which it had been made available. The instrument was, he said, used for infantile paralysis and diphtheria where the respiratory muscles were involved. Other indications were partial electrocution, gas poisoning, drug intoxication, drowning, and alcoholic coma. Research would, he felt sure, reveal yet further indications for its use.

The history of the Drinker respirator begins in 1929, when the engineer whose name it bears and Dr. L. A. Shaw demonstrated the invention at the Harvard University School of Public Health, and instructed Dr. G. P. Crowden in its use. In 1931 Professor Drinker brought over the latest type of respirator to this country. Messrs. Siebe Gorman, whose attention had already been drawn to the uses of the apparatus, undertook to modify the motors to suit the requirements of hospitals, and the apparatus was taken successively to Bart's, University College, Oxford (where it saved the first life in this country), and the National Hospital, Queen's Square. In October last year Dr. Stowell and Major Freeth of Imperial Chemical Industries made it possible for a specially adapted apparatus to be presented to Great Ormond Street Hospital: this has been made by Gorman's.

Scotland

Neuro-Psychiatric Institute, Glasgow

The annual report of Dr. W. M. Ford Robertson, director of the West of Scotland Neuro-Psychiatric Research Institute, states that this institute has been reorganized and re-equipped in the past year. Certain structural changes were made to provide a separate room for biochemical and serological work, and a complete microphotographical department with dark room. Additions were also made to the permanent fixtures, so that the laboratory is now regarded as fulfilling the most modern requirements. During the year the number of routine investigations carried out at the laboratory was 958, including chiefly flocculation tests and Wassermann reactions. The aim of the institute has been to maintain a critical attitude towards established methods for the sero-diagnosis of syphilis, and more especially towards the Wassermann reaction. The director paid some forty-five visits to the contributing mental hospitals with the object of maintaining contact with their pathologists and medical officers in regard to research. In this connexion an investigation into the calcium metabolism of mental disorders was begun at Hawkhead Mental Hospital. In Woodilee Mental Hospital collaborative work on pneumococcal infections was carried out, and also an investigation by the Schick test on some seventy-three patients and controls, to obtain the incidence of diphtheria suscep-

tibility in mental disorders. In Dykebar Mental Hospital a survey of the Schick test reactions in ninety-four inmates and twenty-one controls was made, while in Stoneycetts Mental Defective Institution the incidence of susceptibility to diphtheria was investigated in over 300 inmates. A preliminary inquiry into the question of allergy, in a small group of epileptics, was undertaken at Lennox Castle Mental Defective Institution. At Riccarton Mental Hospital a detailed investigation on leucogenesis in the manic-depressive group of the psychoses was carried out by making a four-hourly survey of the leucocyte condition in seven cases from the day of admission to discharge; this research entailed some 2,000 individual counts, and the findings were given in a paper before the Royal Medico-Psychological Association. The financial statement shows that the expenditure of the institute for the year 1933 amounted to £2,249, with a revenue of £2,142.

Deaconess Hospital, Edinburgh

Presiding at the annual meeting of the Deaconess Hospital, of the Church of Scotland, held in Edinburgh on March 23rd, the Rev. Alexander Fiddes said the hospital had sustained a very great loss in the death of Lord Sands, who had been on the Board of Management for thirty-three years and chairman for twelve years. He had been an outstanding man of his generation, a distinguished judge, a great churchman, and a great citizen, and his humanity had brought him into touch with many movements of the time. In submitting the annual report the chairman stated that 891 adult patients had been treated in the hospital during the year and 329 infants and children in the children's ward. There had been over 6,000 out-patients, and the district nurses attached to the hospital had paid 2,506 visits, chiefly to maternity cases. For several years it had been realized that the present building was inadequate, and the hospital had recently acquired, from the Edinburgh Corporation, a piece of ground and a vacant police station, both adjoining the hospital, at a cost of £4,000. The contemplated improvements would cost over £30,000, of which £7,000 was already in hand. The Board of Management had still to approve the scheme, which included remodeling the present building, additional nurses' quarters, an enlarged out-patient department and children's ward, and a new operating theatre. After plans had been approved an appeal would be made to the public.

Aberdeen Royal Mental Hospital

It was stated at the annual meeting of the Aberdeen Royal Mental Hospital, on March 21st, that the revenue of the institution had amounted in the past year to £63,700, which was £2,000 less than in the previous year. Expenditure, however, had been reduced to £61,100, so that the year's working showed a surplus of £2,600. Progress was being made with a scheme of reconstruction and extension, which, it was estimated, would cost somewhat more than £100,000. The annual report of Dr. Dods Brown, physician-superintendent, emphasized the need for early treatment in mental illness, and the high percentage of recoveries that resulted when patients and their friends took early advantage of the opportunities afforded for treatment. He also emphasized the grave danger to the community which resulted from the full freedom allowed to a large number of mental defectives.

Glasgow Samaritan Hospital for Women

At the annual meeting of the Royal Samaritan Hospital for Women, Glasgow, Professor J. M. Munro Kerr expressed the view that the future of voluntary hospitals depended upon an extension of their paying blocks. Unless these were established voluntary hospitals would

be swept under the care of the local authorities. The more pay-beds there were in a hospital the more efficient would be the service of the non-paying part of that hospital. It was stated at the meeting that the hospital had had to transfer £3,000 from extraordinary income to make good the deficiency in the past year's ordinary revenue. The deficiency had arisen partly from diminished subscriptions and partly from reduced interest on securities held as capital. A proposal had therefore been made during the year to establish paying wards. Principal Sir Robert S. Rait said the hospital could only continue its good work by increasing its resources through the addition of paying wards. Such wards were, he said, a very real need of our time.

Aberdeen Maternity Hospital

At the annual meeting of the Aberdeen Maternity Hospital it was intimated that the directors had decided to proceed at once with the erection of a new maternity hospital at Foresterhill. Owing to financial stringency, however, the accommodation of the new building would, for the time being, be restricted to thirty-four beds; ten further beds might be added later. The cost of the proposed hospital was estimated at over £40,000, exclusive of furnishing and equipment; of this £27,000 was already in hand, and a grant of £7,500 had been promised from the Ross-Crombie Fund if the directors speedily raised the remaining £5,000.

Ireland

Royal Maternity Hospital, Belfast

The first annual meeting of the new Royal Maternity Hospital was held in the King Edward Memorial Hall, Belfast, with Professor R. J. Johnstone presiding. The annual report states that the new Committee of Management, nominated by the Boards of the Incorporated Belfast Maternity Hospital and the Royal Victoria Hospital, was appointed in January, 1933. A period of the strictest economy was observed; nothing was bought that could be done without, and many articles of equipment which would otherwise have been discarded and replaced were made to do service for another month or so. The expenditure for the five months in the new hospital was £3,364 13s. 4d., and the income, not including a £1,000 loan from the Royal Victoria Hospital, was £3,523 16s. 7d. There was thus a small credit balance of £159 3s. 3d. The annual cost of the hospital will be approximately £8,200. This figure does not cover heating, laundry, and telephones: these services are supplied by the Royal Victoria Hospital. The medical report states that 1,157 patients were admitted to the two hospitals during the year, including sixty-six patients to the Rea Block (the septic ward) in the Royal Maternity Hospital. There were 821 babies born in the hospital, and twelve mothers died. Of the latter, five were ante-natal patients, two dying from pneumonia during an outbreak in the hospital in the early months of 1933, and the other three from shock, severe anaemia, and cardiac disease. The death rate among ante-natal patients was 0.59 per cent., but among patients admitted as emergency cases it was 3.6 per cent. The ante-natal department continued to be well attended, with 1,500 new patients and 5,051 reattendances, making a total of 6,551. The number of ante-natal patients admitted to the hospitals was 912, fifty-three of whom were in hospital on more than one occasion. Professor Johnstone, in moving the adoption of the report, paid tribute to Colonel Forrest, Mrs. Herbert Ewart, and all those who had done

laborious and useful work in connexion with the old hospital and the new Maternity Hospital. The committee of management of the new hospital had named a ward in acknowledgement of the services of the Ewart family to the institution. He also thanked those who had helped to raise funds for the building of the hospital, and in this connexion it was only fitting that he should mention especially the Duchess of Abercorn, who continued to show great interest in the institution, and had intimated her readiness to come and receive the gifts on the hospital's first pound day. In conclusion, Professor Johnstone referred to the committee formed last August to further the interests of the Royal Maternity Hospital. It had taken the name of "The Gleaners," and its aims were to help the Management Committee and save expense wherever possible, and to raise funds in various ways.

Amalgamation of Dublin Hospitals

Sir John Lumsden presided at the seventy-second annual meeting of the governors, subscribers, and friends of the Convalescent Home, Stillorgan, held in the Royal College of Physicians of Ireland. The report submitted to the meeting stated that the number of patients admitted during the year was 627, an increase of eighty over the number for the previous year. The Committee of Management, however, much regretted the continued falling off in the number of subscribers, due no doubt to decreased income and to the deaths of previous subscribers. Acknowledgements were made to the Dublin Hospital Sunday Fund for its grant of £260 2s. 8d., and to the Dublin Corporation for £133 6s. 8d. The statement of accounts showed an excess of income over expenditure of £687 5s. 9d. In moving the adoption of the report and statement of accounts, Sir John Lumsden said that the Dublin hospitals had been passing through a rather anxious period, but the Hospitals Sweepstakes Fund, with its wonderful organization, had practically placed them on their feet again. Many hospitals held out for a long time in the hope that they could continue to be maintained as charitable institutions, supported as of old by voluntary subscriptions; but when the sweepstakes came along subscriptions fell off, and nearly all the hospitals were driven into participation in the sweepstakes fund. A commission had been set up to consider the whole problem of hospitals in the Free State and to report to the Government. For a long time he had been in favour of the amalgamation of certain hospitals. No city of equal size had as many hospitals as Dublin. Many of them, however, were badly constructed, could not be modernized, and were more or less out of date. He hoped the commission would consider this question of the amalgamation of certain hospitals. If four or five of them were scrapped, and a new one built with, say 500 beds, opportunity would be afforded for better and more up-to-date treatment and diagnosis. The patients would benefit, and if the new hospital were endowed more free cases could be admitted, and there would be improved teaching facilities. In any scheme which might come before the commission he hoped there would be provision for convalescent home treatment.

Diphtheria in County Dublin

Dr. J. A. Harbison, medical officer of health for County Dublin, reported an outbreak of diphtheria in Clondalkin and Rathcoole during the period March 5th to 15th, twelve cases having been notified to date. One child had died, another was dangerously ill, and a school had been closed. Dr. Harbison considered that the public should be warned to seek medical attention immediately a child complained of sore throat, especially if the sore throat was associated with headache or other symptoms.

Reports of Societies

PATHOLOGY AND TREATMENT OF LYMPHADENOMA

At the Section of Medicine of the Royal Society of Medicine on March 27th, with Sir FARQUHAR BUZZARD in the chair, a discussion took place on recent advances in the pathology and treatment of lymphadenoma.

THE PATHOGENIC AGENT

Dr. MERVYN H. GORDON limited his opening remarks to the pathological side. Lymphadenoma, he said, formed a link between granulomata of known aetiology and malignant disease. Its aetiology, therefore, might well be a key position, opening up the possibility of a successful attempt on sarcoma, the form of malignant disease nearest to it. It had been described as a specific disease affecting primarily the lymphatic glands, and spreading to other organs. When the three characteristic changes—fibrosis, giant cells, and eosinophils—were all present the evidence for lymphadenoma was complete, but in practice many cases occurred in which one or more of these three changes were lacking. There might be proliferation of the reticulo-endothelium without typical giant cells, or the fibrosis and eosinophils might be absent. There seemed to be a series of gradations between typical lymphadenoma and typical lymphosarcoma or reticulo-sarcoma. The term "Hodgkin's group" seemed to be a convenient one for these conditions until more was known. Such incomplete knowledge as had been gained with regard to lymphadenoma depended upon clinical methods and anatomical pathology (macroscopic and microscopic). On the other hand, there was a definite disease with specific clinical and histological features which enabled it to be recognized if reproduced in an animal. The course of the disease was suggestive of an infective agent, but its apparent uniform fatality tended to bring it nearer to malignant disease than to the granulomata. It seemed possible that when the pathogenic agent did come to light it would be found to be more nearly allied to that of sarcoma than to the granuloma-producing agents at present known.

Dr. Gordon then described the attempt which had been made during the last six years, with the co-operation of the staff of St. Bartholomew's, to obtain further light on the aetiology. This work had proceeded along three lines: (1) the search for a pathogenic factor in the glands removed from lymphadenoma cases; (2) microscopic studies of this material for the presence of an organized agent; (3) allergic tests. So far as possible the procedure had been from the known to the unknown, and the results had been checked by the examination of control glands from other diseases. In the first place known granuloma-producing organisms were looked for, but cultures remained sterile. No evidence of spirochaetal infection could be obtained, though pseudo-spirochaetes were met with. There was no evidence that the tubercle bacillus (human or bovine) played an important part in lymphadenoma, nor was any confirmation found of l'Espérance's suggestion that the avian tubercle bacillus was the causative agent. Early attempts to produce any effect on laboratory animals by injecting them cerebrally with suspensions of lymphadenoma glands had been unsuccessful, the material probably not being suitable or the dose sufficient. In 1930, however, two Stockholm workers, Hellerstrom and Wassen, reported that they had succeeded in producing meningo-encephalitis in monkeys by cerebral inoculation of pus from the glands of cases of lymphogranuloma inguinale, a benign condition that appeared to belong to the lymphadenoma group. This experiment was confirmed and serial passage obtained. The agent was thus shown to be a virus, and was now established as a cause of lymphogranuloma inguinale. Accordingly, when suitable material from lymphadenoma came to hand, the cerebral inoculation of animals was

resumed, using a more efficient technique. As a result an encephalitic condition, frequently fatal, was found to be produced in the rabbit and the guinea-pig, though not, so far, in the mouse or the monkey. After an incubation period of one to several days these animals might develop symptoms similar to those produced by well-known viruses (vaccinia, herpes, psittacosis)—such as fits, teeth-gnashing, salivation, head-turning, tremors, paresis. Dr. Gordon showed a cinematograph film illustrating the characteristic movements. The first step was to see whether this curious action of lymphadenoma glands on the rabbit's brain could be applied for diagnosis. This matter had been under investigation now for three years, during which time glands from all sources, but chiefly those removed for biopsy in cases in which on clinical grounds lymphadenoma seemed possible, had been submitted to the rabbit test. It was plain that this biological test was capable of performing useful service in the diagnosis of lymphadenoma. So far he could recall only three cases in which a mistake had been made. In all of them the error was one of interpretation, a weak passage with a raw material alone being regarded as positive. In typical cases the reaction was pronounced, both with the raw material and with the same after it had been heated for thirty minutes to 65° C. The value of the test for diagnosis had been confirmed, in Edinburgh, by van Rooyen, who had obtained positive results in fifteen out of twenty cases of lymphadenoma, and negative results with glands from other conditions.¹ The test seemed to be of chief value in early cases of lymphadenoma. Later, when the disease had become chronic, the glands not infrequently gave negative results. The strongest reaction seemed to occur when all the three cardinal histological changes mentioned at the beginning were present in the glands. The nature of the pathogenic agent concerned in this aetiological reaction had not yet been settled. Its pronounced thermostability distinguished it from most of the known viruses, though not from all. Its presence in a given suspension increased as time went on, apparently from autolysis of the cells, and in glands from acute cases it could then be detected sometimes up to a dilution of 1 in 200. With such material he had confirmed van Rooyen's observation that it was filterable through bacterial filters such as the Seitz.

In view of Friedemann's interesting observations² the speaker had recently examined specimens of marrow, and found that the foetal ribs and spleen contained neither a proteolytic nor an encephalitogenic agent. A child's ribs at term were equally negative. By the thirty-third day, however, both agents were present in the rib marrow, and eight out of ten adult rib marrows were also positive in both respects. Pus gave almost, if not quite, as high a proteolytic titre as marrow, and all of eight specimens tested gave high readings, yet, when injected into the rabbit's brain, six of them were negative. The two positive specimens came from a case of pneumococcal empyema following appendicitis and from one of staphylococcal osteomyelitis. Although in some of the rabbits inoculated cerebrally the symptoms very closely resembled those produced by lymphadenoma glands, it seemed to him that in most of them the chief effect was one of paralysis, far more so than was usually the case with lymphadenoma gland suspensions, and he was not satisfied that the conditions induced were identical. Through the kindness of Colonel Hamerton he had recently been able to test rib marrow from a bear and a leopard. Both gave good proteolytic readings, but neither of them contained an encephalitogenic agent for the rabbit. The problem of the relation of these two agents, therefore, was complex, and required further investigation. The manner in which they acted was also at present obscure. If they eventually proved to be identical, then Medlar's hypothesis that lymphadenoma was primarily a malignant disease of the marrow would receive support. Whatever the outcome might be, the presence in marrow and pus of an encephalitogenic agent did not invalidate

² *Ibid.*, March 24th, 1934, p. 517.

the diagnostic value of the rabbit test when applied to glands from suspected cases of lymphadenoma. Recent work on vaccinia had proved that the well-known elementary bodies of Paschen were the actual virus of that disease. It was of much interest, therefore, to find that bodies closely resembling these vaccinia bodies were present in large numbers in suspensions of lymphadenoma glands. Dr. James Maxwell had also tested cutaneous allergy of lymphadenoma cases. The results with tuberculin were negative, and with extract of fungi no evidence of specific allergy was obtained. Wilson Smith had shown that a boiled extract of tissues containing vaccinia virus excited the specific allergic reaction in the skin of previously vaccinated persons, and therefore an extract on similar lines from dried lymphadenoma glands had recently been tried on lymphadenoma cases. He left it to Dr. Gow to refer to the results.

SOME CLINICAL OBSERVATIONS

Dr. A. E. Gow reminded the Section that this subject was last considered by the Society in 1926. He had nothing to add to what Sir Humphry Rolleston had said on that occasion on behalf of the Section of Medicine with regard to terminology, but the last few years had shown that the term "lymphadenoma" did not denote a single disease, but several morbid processes, much alike in their general characteristics, but yet showing minor differences in their symptomatology, course, prognosis, and therapeutic response. Sir Humphry Rolleston had said, eight years ago, that the cause of Hodgkin's lymphadenoma was unknown, so that it was necessary to fall back on its histological structure as the only means of defining exactly what was meant by the name. The possibility that lymphadenoma was a virus infection was beginning to receive considerable laboratory support, but clinically the disease bore no resemblance to other virus conditions in man, except granuloma inguinale. Dr. Gow described a number of cases, which he illustrated with photographs, x-ray pictures, and microscopical sections. One patient, a female aged 28, developed severe pruritus, which symptom persisted until her death from lymphadenoma three years and eight months later. She was treated by radiation, arsenic by three routes, and iron, but nothing was found to control the pruritus. Histological and biological tests were positive for Hodgkin's disease. The first attempt at specific therapy was with a chicken serum, but the conclusion was reached that the treatment was of no avail, and the same conclusion was recorded by other workers. In some cases the patients felt better after the injection, but the effect on the progress of the disease was disappointing. Later in this case a suspension of the patient's own glands, attenuated by 10 per cent. ether, was administered intramuscularly. This extract eased the pruritus for twenty-four hours, but was followed by an appreciable swelling of the nodes in the neck and face, which ultimately broke down. It was therefore justifiable to assume that the extract contained some active agent. Another patient, aged 30, had been under observation for three and a half years. She had a pendulous swelling on the right side of the neck. The gland histologically showed the typical Hodgkin's lesion. Tonsillitis was followed by swollen glands on the left side of the neck, which never subsided, and erysipelas in the left arm shortly preceded the development of a painful swelling in the left axilla. The sequel to a second bout of erysipelas involving the chest and left arm was the breaking down of glands on the right side of the neck, and later in the axilla, and the formation of very large fungating granulations. On the first occasion the pus aspirated was sterile, but later haemolytic streptococci and staphylococci were isolated. The patient was given two courses of sensitive vaccine prepared by Dr. Gordon. The first dose was followed in half an hour by a sensation of tingling in the glands of the neck, but injections on following days caused no obvious local or general disturbance. The spread of the disease, however, was not arrested. The case of another female patient presented many features of interest. Her father was

reported to have died of the disease five years before the daughter became affected. The mother contracted an acute form of the disease four years after the daughter, and died in eleven months. The death of the daughter took place four years and eight months after the gland was noticed.

With regard to the intradermal allergic test referred to by Dr. Gordon, Dr. Wilson Smith had demonstrated that a boiled extract of vaccinia virus prepared by his method was efficacious when injected intradermally. Lymphadenoma might be a virus disease, and the experiment had been repeated, using as antigen a boiled extract of dried lymphadenoma gland, prepared by Wilson Smith. No reaction was obtained with the first antigen prepared from raw lymphadenoma gland, but the gland dried *in vacuo* was next extracted in the same way, and had been tested on some thirty patients, of whom ten were controlled and all negative. The great majority of cases known to be suffering from Hodgkin's disease had always proved negative to the test, but in three cases in which the disease appeared to be resting a small local reaction appeared in twelve hours. The best reaction of all, however, measuring 3 cm. in diameter, occurred in the case of a female, aged 34, whose gland showed histologically definite evidence of lymphadenoma, but gave a negative biological test. This patient had been ill for more than three years. She suffered much from pruritus.

Concerning the effect of modern treatment, mainly irradiation, Dr. Gow said that there could be no doubt that life was prolonged, and, what was perhaps more important, the periods of remission, particularly in the earlier stages of the disease, were lengthened, and the patients were able to resume their occupation seemingly well.

X-RAY TREATMENT

Dr. W. M. LEVITT sent a communication, which was read in his absence. He said that x-ray treatment of this disease presented many essentially medical problems. Further progress could only result from the help afforded by physicians and pathologists. When presented with a localized focus of lymphadenoma the radiologist could practically promise its disappearance with adequate x-ray treatment. The extent to which this process could be carried was only limited by the amount of x-ray energy which could be safely poured into the body. In spite of the success of x-ray treatment, however, lymphadenoma could not be cured by x rays, except, perhaps, in very rare instances. Recurrences appeared, either in the initial site or other glandular areas, and although these recurrent lesions also responded to x-ray treatment sooner or later, the disease became widely disseminated in the chest and abdomen—so widely disseminated that the x-ray dosage that would be necessary to secure regression of all the lesions could not be applied. The treatment was, however, frequently successfully undertaken for the relief of pain and other pressure symptoms even at this stage, and until late in the disease the characteristic cachexia improved along with the disappearance of the local lesions.

After the initial treatment the time which might elapse before recurrence varied greatly. Only too often it was a matter of a few months, but occasionally the patients might remain in health for one, two, or more years. The intervals became shorter with successive recurrences, and in the end the disease became more resistant. When the disease was generalized the duration might be measured by weeks rather than by months. The failure to maintain the x-ray results obtained in the early stages of lymphadenoma was one of the most disappointing things with which radiologists had to deal. Probably they had been too ready to assume, when their attention was first called to a lymphadenomatous mass in a given region without evidence of disease elsewhere, that the palpable mass must be the initial focus of the disease. Was it possible that the initial focus was really in some of the deeper glands, and the first discoverable lesion was really a secondary deposit? If it could be shown that in a substantial percentage of cases the disease began in

a certain group of glands, there would be a glimmer of hope that, if such a group were adequately irradiated, at least a certain number of cases would result in permanent cure. Arguing on these lines, the rare instances of cure by x rays could be explained on the supposition that the lesion to which the rays were applied was really the initial lesion.

For many years it had been taught that the mediastinum should be treated in every case, and that had been his practice at St. Bartholomew's. The difficulty arose, however, over the consideration as to whether the abdomen should be included in the irradiation, because of the effect on the patient's general condition. The effects of x-ray treatment on the abdomen, especially when such treatment was also being applied to other parts, were quite severe. So far it had not been the practice to apply x rays to the abdomen as a routine treatment. With regard to questions of dosage, the masses disappeared with doses of suitable quality which were considerably below the tolerance doses of the skin and other healthy tissues. He believed that nothing was to be gained by increasing the dosage in the hope of arresting the inevitable march of the disease. Efforts made in recent years to improve the results of x-ray treatment had consisted in methods of regional irradiation, to which Finzi had applied the term "radiation bars." These entailed the exposure of large regions to repeated small amounts of radiation, and it was known what dosage might be safely tolerated in the abdominal and thoracic bars.

GENERAL DISCUSSION

Dr. ULRICH FRIEDEMANN repeated some of the conclusions given in his paper published in the *Journal* of March 24th (p. 517), and indicated some doubts as to the nature of the agent. He also pointed out that it had now been demonstrated that the agent which was pathogenic for rabbits was present not only in human bone marrow and spleen, but also in human leucocytes. Dr. VAN ROOYEN also described some of the work set out in his paper in the same issue (p. 519). There were three factors to be considered with regard to the pathogenic agent: (1) that it was a living agent of the ultra-microscopic class in the cell; (2) that it was some toxic product of the living agent; (3) that it was a ferment. In the absence of inclusion bodies and of transmission it could not be said to be a virus infection; but nevertheless animal transmission had never been satisfactorily established in such well-known bacterial conditions as typhoid. It was possible that what was being investigated was a virus exhibiting a high degree of specificity for lymphoid tissue which it would never be possible to produce in the experimental animal. Dr. F. PARKES WEBER wished to put forward another possible explanation of Hodgkin's disease. He was familiar with the arguments for an infective origin, but he did not believe the evidence was by any means conclusive, and there was just as much probability that Hodgkin's disease was neoplastic—meaning by a neoplastic disease the proliferation of a cell or a system of cells which served no useful or conservative purpose for the organism, and so might be benign or malignant. In this class he would include myelosis, lymphadenosis, and Hodgkin's disease. He did not speak with dogmatism, but suggested as a possibility for discussion that Hodgkin's disease was a more or less malignant proliferation of the reticulum, and he would name it "reticulomitosi," separating it from other conditions to which the word might be applied by giving it the prefix "Hodgkin's." There was no type of Hodgkin's disease which could not be explained as a more or less malignant neoplastic disease of the reticulum, because the reticulum was able to, and did, form all the cells which occurred in every type of Hodgkin's disease.

Dr. MERVYN GORDON, in reply, admitted that as yet there was no conclusive evidence as to the aetiology from the laboratory point of view—to one person a virus was suggested, to another a toxin, and to a third, possibly, a proteolytic agent—but he thought some progress was being made.

FUNCTIONAL DISORDERS OF THE BOWEL

At the meeting of the Medical Society of London on March 26th, with Mr. R. DAVIS-COLLEY in the chair, the subject for discussion was "Functional Disorders of the Bowel."

Dr. T. L. HARDY of Birmingham, in opening, said that the subject was not only a large one, but somewhat confused. There was hardly any specialty, qualified or unqualified, which had not contributed something—and often something harmful—to the study of these disorders, which were, indeed, the happy hunting ground of the specialist, and too often the despair of the general physician and practitioner. He confined his remarks to the colon, the dysfunctions of which stood in need of some clarification. Terms such as visceroptosis, atonic constipation, perhaps even spastic colon, were often inaccurate, and did but emphasize different views of the same essential disturbance of muscular imbalance. With regard to ptoses in general, one authority declared, many years ago, that there was no more harm in a dropped kidney than in a dropped "h," and that represented the modern position regarding the colon. The passage of food residues through the colon by mass movements showed remarkable variations in health by whatever method it was examined, and it was well-nigh impossible to define the border-line between orderly and disorderly function. The function of the colonic musculature was the maintenance of tone. Surgeons were familiar with areas of contraction occurring in short lengths of exposed bowel; it was difficult to know what significance was to be attached to the areas of local spasm as revealed by the radiograph. Knowledge of colon function, so far as this aspect was concerned, was very limited. The results of sympathectomy in such conditions as Hirschsprung's disease were promising, though as yet little beyond the experimental stage. Disorders frequently manifested themselves in a soil prepared through the agency of an unstable nervous system. Dr. Hardy divided the disturbances into four groups of "unstable colon": (1) hyperirritability; (2) hypertonicity, either of certain sphincters or general or local spasm of the colon; (3) hypo-irritability and hypotonicity of the colon, either generalized or localized; and (4) achaliasias.

The frequency of functional disorders of the colon was difficult to estimate. Hospital statistics gave little help: the intestinal neuroses diminished in frequency as the social scale descended. The figures of certain observers in England and America showed that functional disorders of the colon accounted for 20 or 30 per cent. of the total of abdominal conditions. Female patients preponderated. In his own series of 157 cases, the females numbered eighty-nine and the males sixty-eight—a much higher proportion of the latter than had usually been recorded. It was now realized that males were beginning to take their place among these colonic dysfunctional cases with greater frequency than formerly. Early middle-age seemed to be the period of greatest prevalence; fifty-one of his patients consulted him between the ages of 30 and 40, and the remainder were spaced with more or less uniformity between the ages of 20 and 60. Of these 157 patients 106 complained of constipation, but of that number seventy-four were submitted to a barium meal examination, and actual delay was discovered in fifteen cases only; in the remainder the colon emptied in normal time. No fewer than seventy-seven patients were taking irritant aperients, commonly vegetable laxatives and preparations containing phenolphthalein. A preparation called agarol was widely used; its manufacturers described it as dependable, and so it was, but its continued use was distinctly harmful. These purgatives were of undoubted value for occasional use, but for daily use they could not be too strongly condemned. Abnormal mental reactions were characteristic of many patients with colonic disorder. This abnormal mental reactivity was frequently associated with a particular state of nutrition, as in tall and thin individuals. The link between the causative factor and the clinical manifestation in these disorders was still a

matter for speculation. There was practically no experimental evidence to support the view that chemical or bacterial toxins were absorbed from the colon in so-called intestinal stasis in sufficient amounts to cause symptoms. Food allergy was a very real thing, and in its acute form well recognized. In his own series a familial or personal history of migraine was obtained in three cases only, and of asthma in one. There was certainly a danger in the too facile diagnosis of allergy. It was well known that the chronic intestinal invalid was unable to tolerate certain articles of food, and little was gained by attributing obscure symptoms to equally obscure phenomena. The symptomatology of functional disease of the colon was varied. It was often sufficiently characteristic to enable a diagnosis to be made with confidence from the history and the manner of its telling alone. The symptomatology was both local and general. The local symptoms had reference to the gastro-intestinal tract; the general symptoms manifested themselves particularly in the nervous and cardiovascular systems. Pain of colonic origin was usually referred to the lower abdomen. In his own series there was abdominal pain on the right side in forty-three cases, on the left side in thirty-eight cases; there was epigastric pain in forty-nine cases, this being aggravated by food in eight, improved by food in twenty, and uninfluenced by food in twenty-one. The disorder known as muco-membranous colic was fast disappearing, and one was tempted to hope that modern teaching on the harm of the purgative habit was bearing fruit. The general symptoms showed themselves as fatigue or irritability of the cardiovascular system, and vasomotor disturbances, such as palpitation. Temporary dyspnoea and coldness and blueness of the hands and feet were occasional complaints. He emphasized that many of these patients were suffering from something more than a disordered colon, and just as diagnosis involved a greater responsibility than the determination of the behaviour of the lower bowel, so must treatment aim at arresting the primary cause and not be content simply with the relief of the local symptoms.

THE SPASTIC COLON

Dr. THOMAS HUNT said that of ninety-three cases of simple indigestion without organic lesion he had grouped sixty-two under the heading of irritable spastic colon. The symptoms were extraordinarily varied, and often the most severe cases might show little by radiography or other examination. Similarly, there might be very gross organic lesions of the bowel with very few irregularities and symptoms referable to them. Displacements might be very extreme with normal function. Of the symptoms he wished only to mention one of two which afforded help in differential diagnosis. The first were the increase of discomfort in cold and the frequency of backache, both of which were particularly common in these cases of irritable colon. Another symptom he had met with in a good many cases was multiple generalized aching or bruised sensations in the muscles, which was generally described by the patients as rheumatism, and treated as such. Another characteristic symptom was a sensation of incomplete defaecation, which he believed in many of these cases to be a purely mental obsessive feeling. Frequency of micturition was also a common symptom. Nevertheless, he thought that sometimes a full bladder might be capable of exciting colon spasm. Loss of weight and vomiting sometimes occurred to a very severe degree, and were particularly increased by injudicious handling from the psychological point of view. He remembered one patient who vomited steadily for five days, simply because the nurses and the doctor had managed to give her the impression that she was not trying. On examining a case of irritable spastic colon there were three main points of tenderness in the right iliac fossa, and often in the left iliac fossa, and the epigastrium—over the sigmoid, over the caecum, and over the abdominal aorta.

Causes might be considered under four headings: reflex, from organic disease elsewhere in the abdomen; bacterial, with organisms in the colon itself; allergic factors; and

nervous factors. The last category was by far the most important, and he gave particulars of certain cases which had convinced him of the significance of the nervous factor. With regard to bacterial infection, he had gone through a number of the cultures in twenty-six of his cases with irritable colon, and had found nothing significant; the organisms of greatest frequency were the non-haemolytic streptococci. The importance of bacterial infection might be overstressed and do great harm, by fixing the patient's attention upon some physical illness. With regard to the abuse of purgatives, there was also here a big nervous element. On going through seventy-five cases of patients whom he had seen for other than digestive disorders, he found that thirty-seven had taken purgatives every night for years, and were in no way adversely affected. They complained of no symptoms referable to the bowel. He believed there must be some added nervous factor as well as the abuse of the purgatives before marked symptoms were produced. He drew attention to the character of some of the literature broadcast. One circular stated: "A clean colon spells youth, power, and magnetism and brilliance in society." That sort of bait was a very clever one for people who were, in fact, of the inferiority type. Another statement was: "It is the accepted verdict of medical authorities that appendicitis is entirely due to constipation." What a powerful stimulus to fear was such a statement as that in the right kind of subject!

From the point of view of treatment it was important to distinguish between cases of local reflex origin and true psychoneurotic or emotional cases. Mere psychological treatment was likely to have little influence on cases of true reflex habit spasm; on the other hand, the true psychoneurotic patient could be very much helped by reassurance and explanation. Of the psychological causes in his own series the most important was fear. This could be a potent cause of colon irregularity. Fear of organic disease was frequent, though not as common as was sometimes believed, and it was well to remember that in only a proportion of cases would the assurance that there was no organic disease be effective. Sometimes there was a fear of insanity, also a sense of guilt, as, for instance, after masturbation. Another important cause was frustration, especially of the sex instincts among unmarried women; and, again, there was the "kicking against the pricks" of many middle-aged persons carrying on uncongenial work in a hopeless environment. He mentioned a case of one young married woman who suffered from attacks of severe abdominal pain and diarrhoea at night, with a good deal of indigestion and discomfort during the day. When he attended her he found that to get to her bedroom he had to pass through a corridor of coffins, her husband being an undertaker, and no doubt these macabre surroundings had influenced her malady. Another case, also that of a young married woman, cleared up completely after the death of her mother-in-law, who had lived in the household and had dominated her. Lack of work was sometimes a cause, and many of these cases occurred in patients who had little to do. Harm was sometimes done by the advice of doctors that the patient should have a long holiday, no account being taken of the choice of company, or the worry which might follow from the thought of loss of work and income. A faithless husband could be a more frequent cause of colonic irregularity than a host of bacteria, and a study of Marcus Aurelius might be as good as a dozen colon washouts with antiseptic solution. He believed that the diet should be as free as possible. The only important restrictions were hard residue-forming substances, like nuts and peel, and some restriction in the starchy and cellulose foods. It was probable that emotional causes might inhibit bowel motility and secretion, and the use of sedatives was comparable to the use of morphine in some cases of paralytic ileus by cutting off the nervous inhibitory impulse. He had found in some cases nitrites to be of value. He had tested adrenaline in a number of cases, and in quite a big dose subcutaneously he had not been able to show that it had produced any marked alteration in bowel tone. In a few cases insulin might be useful. Some appreciable gain in

weight in the undernourished type of person was of value as a psychological encouragement.

PHYSIOLOGICAL ASPECTS

Dr. A. F. HURST drew attention to some points in the physiology of the colon and what ought to be regarded as the limits of the normal. It was absurd to think that the appearance of mucus in the stools was a sign of disease, and that the case should be regarded as mucous colitis. Mucus was the only normal secretion of the colon, and it was secreted wherever the colon was irritated. The passage of mucus with solid matter was a perfectly normal phenomenon. Mucus was secreted in excess when the mucous membrane of the bowel was irritated by aperients. It could only be regarded as an abnormal constituent if it was associated with looseness or diarrhoea which had not been produced as a result of an aperient. Again, it was not sufficiently realized that the whole of the colon, even the caecum, took part in a normal defaecation. The vast majority of cases of constipation, if not all, were really due to deficient defaecation. Normal defaecation was a conditioned reflex, whereby the whole of the colon emptied, and if this reflex disappeared constipation of one sort or another developed. The cases could be cured by retraining the conditioned reflex. Sympathectomy was theoretically a good operation, but it did nothing more than relax the sphincter, which could be done in a less drastic way. Intestinal allergy was a rare condition, but a very important one. Although adrenaline had no obvious effect on the colon musculature, small doses would cut short an allergic attack almost immediately.

Dr. G. VILVANDRÉ, who showed some radiographs to illustrate his points, said that it was rather fallacious to look upon the barium meal as very helpful in the investigation of the colon. It could give the time of passage from the mouth to the anal canal, but not much valuable information on the appearance and function of the transverse colon. The best way to obtain a view of the colon was by giving a barium enema. A good surgeon would say that the best method was sigmoidoscopy, and as a radiologist he was inclined to agree with him. But after the sigmoidoscopic examination much could be learned from a study of the radiograph with the barium enema. He also stressed the fact that spasm of the ileo-sigmoid region did not necessarily remain functional always, and yet did not indicate carcinoma; it might be due to diverticula. He insisted that cases of alternating constipation and diarrhoea should be thoroughly investigated, and not regarded offhand as functional.

Mr. EARDLEY HOLLAND remarked on the extreme interest of these functional cases in gynaecology. Many women who came for supposed gynaecological lesions had this colon trouble, often as the result of emotional disturbance, a frequent characteristic in cases which appeared in the gynaecological consulting room. Retroversion of the uterus was often found in women who had spasm of the colon. In pregnancy these pains, especially in the right iliac fossa, were very common, and a great many women during pregnancy had their appendix removed for no better reason than these spasmodic pains.

ÆTIOLOGY

Dr. CAMPBELL McCLURE said that the nervous trouble might be one of two kinds: either strain over a long period or repeated emotional stress. But there were many people who had these strains and stresses without suffering any dysfunction of the intestine, and he thought that in those that did there must be an inborn imbalance of the vago-sympathetic relation. A spastic condition of the intestine might be induced not only by emotional excitement but by the exhaustion of the poisoning of the vagus centres. He also suggested that a colon which had lost its tone might act as a drag upon important ganglionic centres and produce reflexes of the most amazing kind. Retroversion of the uterus was not uncommonly, in a sensitive person, the apparent exciting

cause. One had always to remember, in the treatment of these patients, that, as they were naturally of a neurasthenic type, their suggestibility was extraordinary; and it was necessary to be careful not to attribute too much to actual treatment and too little to the effect of reassurance and the general strengthening of the attitude towards life.

Mr. W. McKIM McCULLAGH remarked that most gynaecologists declared that retroversion did not cause any intestinal or internal troubles; but other authorities had stated that in such cases they had found symptoms of indigestion and dyspepsia, the cause, no doubt, being pressure on the organs. The vast majority of patients whom one saw were women of about 45 or 50 years of age who had the common complaint of obesity, probably due to the cessation of ovarian function, but they also complained of intense flatulence. Whether this was due to lack of calcium or deficiency of mastication he had not made up his mind, but it was very commonly found among women at that time of life. Dr. CHARLES NEWMAN suggested that there were two groups of common bowel disorders. One of these was the group in which the bowel only was affected, and the other the group in which the bowel and other organs were effected. Cases in the first group, in which the disorder was limited to the bowel itself, were, he thought, emotional in origin, and here the incubus of the organic school was still too heavy. Concerning the second group, he said that, while investigating functional disorders of the gall-bladder and biliary tract, it was borne in upon him strongly how often these patients had colonic disturbances. He had also found irregularities characteristic of the vaginal region which were associated quite definitely with a spastic state of the colon. The colon part of the disorder did not respond to treatment with belladonna in anything like the way in which the rest of the condition did. When functional colon disorder was only part of a disorder of many organs, it was a pity to stress unduly the disorder of the colon. Dr. TWISTINGTON HIGGINS doubted the value of sympathectomy in certain cases.

Dr. J. E. A. LYNHAM drew attention to the extraordinary variations found in the anatomical relations of the pelvis. Complex curves in the transverse colon appeared to him very frequently associated with functional disorders. He had recently seen five cases of undescended caecum with retrocaecal appendix, and all of them presented a picture of colon upset. The patients appeared to him to be subject not to constant but to periodic attacks. They might go for months, or even years, without any disturbance, and then quite suddenly a subacute or acute attack, with pain, distension, and constipation, occurred. He did not wish for a moment to belittle the nervous or psychological element. The fact that in his own personal experience the majority of his cases had occurred in men between the ages of 40 and 55, when the stress of life was perhaps at its greatest, told its own tale. But he believed that the spastic colon was not a purely functional condition. It was due to some anatomical abnormality, which led to functional disturbance, or, more frequently, was associated with adhesion somewhere in the lower bowel. He believed the true spastic colon to be almost invariably due to some organic and not purely functional cause. He also referred to a number of cases which he had seen where the descending colon, instead of following a more or less straight line, took a complicated pattern, in which perhaps eight or ten angles could be counted. One patient had a complete figure of eight just below the splenic flexure, and he had seen cases where some of the intestinal contents were held in one of such loops. He believed that these anatomical considerations entered enormously into the question of functional disease of the colon.

Dr. T. L. HARDY, in reply, said that he fully agreed that cases of alternating constipation and diarrhoea should be carefully examined for any organic disease, if only for the reassurance of the patient. Dr. THOMAS HUNT also wished to correct any impression that he was prepared to attribute these disorders to nervous causes without the fullest investigation.

UTERINE CONTRACTIONS

A meeting of the Edinburgh Obstetrical Society was held on March 19th, with the president, Dr. OLIPHANT NICHOLSON, in the chair.

Dr. CHASSAR MOIR read a paper entitled "Recording the Contractions of the Human Pregnant and Non-pregnant Uterus." He demonstrated three types of apparatus: (1) an intrauterine bag and recording manometer by which contractions of the puerperal uterus could be recorded. (2) An abdominal apparatus which recorded changes in the shape of the uterus. (3) An intrauterine bag which could be used in the non-pregnant uterus. Suckling usually caused strong contractions of the puerperal uterus to appear. Ergotoxine, ergotamine, and the alleged new alkaloid, sensibamine, all caused strong contractions of the uterus, but there was a delay of half an hour or more before any effect was seen after intramuscular injection. This lessened their value in postpartum haemorrhage unless they were combined with a quick-acting drug. Histamine was not effective because in doses small enough to avoid unpleasant flushing effects it had a negligible action on the uterus. Pituitary extract was reliable early in the puerperium, but its effect was very erratic after the first week: in the late puerperium it often failed to produce any activity of the uterus. Liquid extract of ergot (*British Pharmacopoeia*, 1914, and also *British Pharmacopoeia*, 1932) had a powerful, quick action on the uterus, the effect sometimes appearing in as short a time as four minutes when given by mouth. It caused marked spasm of the uterus for an hour or longer. Its action was entirely different from that of the ergot alkaloids. It was this quick-acting factor in ergot which led to its use by midwives 200 years ago. Intrauterine injection of glycerin was not an effective means of causing uterine contractions.

By a double uterine apparatus contractions were simultaneously recorded from fundus and cervix. There was some evidence of a peristaltic wave in the uterus as the contractions of the cervix lagged about seventeen seconds behind those of the fundus. The non-pregnant uterus showed contractions at all periods of the menstrual cycle, but these gradually increased in force from the sixteenth day till the onset of menstruation. During menstruation the contractions exerted a pressure considerably in excess of that seen during parturition. The uterus always responded to pituitary extract. These results were contrary to Knaus's observations published in 1929. Oxytocin (pitocin) in doses of 10 units intramuscularly had no effect on the non-pregnant uterus, whereas vasopressin (pitressin) in the same dose had a very marked effect. In a case of dysmenorrhoea the intrauterine pressure rose to surprising heights. The significance of this in relation to pain was discussed.

CUTANEOUS METASTASES

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland on March 16th, with the president, Mr. HENRY STOKES, in the chair, Professor W. PEARSON showed a case of atypical cutaneous metastases occurring five years after operation for carcinoma of the breast.

Professor Pearson said that the patient, an unmarried woman of 48, had originally presented a firm spherical tumour in the centre of the left breast, with no fixation to skin or muscle and no evidence of enlarged glands. A radical operation was performed, the clavicular fibres of the pectoralis major being preserved. The patient continued in perfect health until a few months ago, when she noticed some small lumps in the scalp and on the skin of the back. On examination there was a hard, circular nodule, one inch in diameter, situated in the skin in the centre of the back. Its surface was reddened, the central part underlying a dry necrosis. Several other small nodules could be seen and felt in the back, most of them appearing to be in the skin, but two seemed partly sub-

cutaneous. A small nodule above the centre of the left clavicle was excised for microscopical diagnosis, and one small pink nodule was present in the skin of the scalp. The operation area appeared quite healthy, and the function of the arm was perfect. No evidence of any other metastases could be found, but radiographic examination of the bones was about to be done.

Mr. R. ATKINSON STONEY said that these metastases seemed to follow one particular system—sometimes the skin, sometimes only the lungs, and sometimes only the abdominal organs. For this reason he supposed there must be some kind of selectivity. Mr. F. J. HENRY remarked that it was interesting to speculate as to the mechanism by which these secondaries arose. He felt that both lymphatic permeation and blood embolism occurred, and had no doubt that bone secondaries, which usually appeared early, were haematogenous in origin. Mr. C. J. MACAULEY drew attention to the fact that the secondaries were so remote from the original lesion. As regards treatment, deep x rays might cause them to disappear, but this, he felt, would only be temporary.

HEART DISEASE AND WORKMEN'S
COMPENSATION

At a meeting of the Medico-Legal Society on March 22nd Mr. D. H. KITCHIN (barrister-at-law) read a paper on "Heart Disease in Workmen."

Mr. Kitchin said that the Workmen's Compensation Acts provided that if personal injury by accident, arising out of and in the course of the employment, was caused to a workman, the employer might be liable to pay compensation to the workman or his dependants. A certain number of workmen, in common with other persons, suffered from grave disease of the heart or blood vessels, from which they might die at almost any moment; a very slight exertion might cause death, or the collapse might come when they were lying in bed. Under the legal position which had been reached through successive decisions of the Court of Appeal and the House of Lords, a workman who died at work from heart disease was nearly always held to have died by accident arising out of the employment, and the widow received compensation. This state of the law, suggested Mr. Kitchin, had not been contemplated by Parliament, was unjust to the employer, and might well cause hardship to workmen through inducing employers to reject men of doubtful physique. After outlining the procedure under the Act, the speaker cited the principal cases which had come before the appellate tribunals since the passing of the first Act in 1897. In *Hensley v. White* (1903), he said, a workman had died of gastric haemorrhage through straining at the flywheel of a gas engine on a cold day. His vessels had been chronically inflamed. The Court of Appeal, following an earlier dictum of Lord Halsbury, had decided that there was no accident, as there had been nothing "fortuitous or unexpected." This decision had been overruled by the House of Lords in *Fenton v. Thorley* (1903), where a healthy workman had ruptured himself straining at a wheel; an accident had then been defined as "an untoward event or mishap, not expected or designed." Whatever the condition of the workman, the employer had to pay compensation if the proximate cause was the work; that the disease had contributed did not matter (*Ismay, Imrie v. Williamson*, 1908). In *Clover, Clayton and Co. v. Hughes* (1910), the most important case of the series, a workman had burst an aortic aneurysm in tightening a nut with a spanner—an act involving the most trifling exertion. The county court judge had found as a fact that the work had contributed to the death, and the House of Lords, by the narrow majority of three to two, had supported his award of compensation: Lord Loreburn, then Lord Chancellor, had proposed the question which had governed the decisions in these cases ever since: "Did the man die from the disease alone, or from the disease and the employment taken together? Broadly speaking, was it the disease that did it, or did

the work that he was doing help in any material degree?" The two dissenting Lords had expressed the opinion that an accident could only be caused by an external influence.

This decision, unsatisfactory in many ways, had led logically to the decisions in *James v. Partridge Jones*, and *Treloar v. Falmouth Docks*, in 1932.¹ In the first of these cases a dipper in a galvanizing shop had died of angina pectoris during a rest period after a morning's work. The judge had held that the work did not contribute, but the Court of Appeal, not satisfied, had ordered a new trial. The second judge had found that there had been no personal injury, but that the man's heart had merely ceased to function; nevertheless, he felt himself bound by the earlier decisions to treat the matter as though the man had undergone a rupture caused by strain. The Court of Appeal had accepted this finding as an award for the widow. In the second case a stevedore had fallen dead during a rest period when sitting on a sack, having just lifted his hook above his head to strike it into another sack. There had been no post-mortem examination. The judge had misdirected himself in finding that there was no accident because there had been "nothing fortuitous," and in not taking into account the whole of the work of the morning. Both the Court of Appeal and the House of Lords had ordered compensation. The Scottish courts, said Mr. Kitchin, still insisted that the widow should point to some specific exertion as the cause of injury, but this view, already rejected by the Court of Appeal, would almost certainly be contradicted by the House of Lords when the first Scottish case bearing on it came before their Lordships. He concluded by drawing attention to the great importance in these cases of the medical evidence, which was necessarily based largely on conjecture.

Mr. W. G. EARENGEY, K.C., said that the law had developed because medical evidence was available to help its growth, and to some extent responsibility rested on the doctor. The judge was practically bound to accept the medical evidence unless it were contradicted, but in the last resort the responsibility for applying the facts to the law rested with the judge. The question of accident was serious, because employers, under pressure from the insurance companies, would not employ men suffering from a known incapacity, and rejected men became "odd lots" on the labour market. Dr. PERCY SARGENT agreed that the state of the law tended to increase unemployment. Medical witnesses should, he said, form conclusions only on certainty, and if they drew inferences should tell the judge they were doing so. Dr. LUTIA FAIRFIELD said that the law had taken the bit between its teeth and run totally ahead of any medical evidence. It did not matter what the medical evidence was, the Act had been turned into a kind of free life insurance for employees. As an intelligent and constructive doctrine of interpretation the decisions were sheer nonsense. Dr. A. S. MORLEY condemned the piecemeal legislation which had led to the anomaly that a workman with lumbago only drew 15s. a week health insurance while a workman with a sprained back might draw 30s. compensation. The result was, he said, confusion and dishonest dealing. Dr. R. K. HOWAR pleaded for a definition of accident instead of mere descriptions. Employers, he said, did not consider medical examination practicable. Dr. D. C. NOMIS remarked that Mr. Henry Ford had all his workmen examined and graded, but never rejected a man for bad health.

Mr. KITCHIN, in reply, said that Lord Atkin, whom he had fortunately met that afternoon, regarded the decisions as just and beneficial. The Law Lords considered that the earlier decisions, if followed, would have led to an unsatisfactory position, and had sought to interpret remedially the words of an Act which they regarded as having primarily been passed to benefit workmen and their dependants. His Lordship would even extend the meaning of "accident" to all industrial disease, including silicosis and nystagmus.

CORRESPONDENCE

Heredity and Mental Deficiency

SIR,—It is much to be regretted that Professor McNeil's article in the *Journal* of March 31st (p. 584) did not appear before the issue of the report of the Mental Deficiency Committee in July, 1932. If his article in the *Edinburgh Medical Journal* of October, 1931, and Dr. John Thomson's article in the same journal of May, 1924, had been before the committee they would have received the attention and criticism which their importance demanded. Perhaps his present article is more relevant to the work of the B.M.A. Committee than to the Report of the Departmental Committee to which he refers. The former committee was restricted by its reference to "the problems of mental deficiency," while the latter had a wider reference, "To examine and report on the information already available regarding the hereditary transmission and other causes of mental disorder and deficiency."

The arresting title "Heredity a Minor Factor in Mental Deficiency" is in direct opposition to the conclusions of both committees. The B.M.A. Committee said (para. 21): "In the causation of mental deficiency heredity plays an important part, but the evidence before the committee does not allow the expression of an opinion as to the exact percentage of cases which can be attributed wholly or partially to this cause." The Departmental Committee said [para. 33 (1)]: "In many cases of mental defect there exists in the family some abnormality—that is, insanity, psychoneurosis, epilepsy, defect, or dullness. In the majority of such cases there is evidence of heredity, but the mode of transmission is at present unknown."

Professor McNeil states that Dr. Thomson did not attempt to separate his clinical types into hereditary and non-hereditary classes. It may be that he did not investigate deeply with this object in view, and was only interested in the variety of clinical types and their aetiology, without going into great detail and inquiry as to family history. If this was not done by Dr. Thomson neither does it seem to have been done by Professor McNeil. Simply to classify 282 simple primary aments as "doubtful hereditary" without going into the family histories with great care for at least two generations can hardly be regarded as evidence that heredity is a minor factor in mental deficiency.

While Professor McNeil's article stimulates thought it also diverts attention from the main problem—Are mental defectives increasing relative to the normal population? The Departmental Committee thinks they are. From this point of view Dr. Thomson's inquiry is not very important. It is not the numbers under 5 years of age but the number who reach adolescence and later ages that really matter. Again, many mental defectives are not recognized until the later years of childhood, and these are more important than those recognized under 5, and are probably more numerous.

I agree with Professor McNeil that the theory of inherited neuropathic constitution is not satisfactory. As there was nothing more definite before them this theory was accepted by both committees. But how are we to get more light on this obscure subject? At the Mental Deficiency Committee I made the suggestion that married mental defectives should be kept in institutions, where the environmental conditions were good and stable, and where they could work at such tasks for which they were fitted. The offspring of such matings could then be observed with accuracy and their condition compared with that of the parents. The suggestion was not received with favour. If it be an offence to human dignity to entertain such a

notion—well, we cannot shut our eyes to the fact that such marriages are being solemnized in large numbers every year in the general community. But surely a sheltered life for married defectives is a humane proposition, and it might yield knowledge that could not otherwise be obtained.

Unless some convincing evidence be built up on direct research on man—animal experimentation is of little use in the problems of mental deficiency—this interminable argument on the force of heredity and the influence of environment will go on until the crack of doom.—I am, etc.,

Warrington, March 31st.

J. S. MANSON, M.D.

Nervous Complications of the Acute Fevers

SIR,—I have read with great interest the account of the discussion on this subject which took place at a recent meeting of the Royal Society of Medicine (*Journal*, March 24th, p. 550)—a meeting which I was prevented from attending to relate my own experience. I can say that this is in accord with that of Dr. Rolleston—namely, that nervous complications are rare in the acute infectious diseases of this country except diphtheria. These complications may be divided into two groups: (1) those due to the essential cause of the disease itself, and (2) those due to an infection with another virus or micro-organism. The complications contained in the first group occur frequently in diphtheria, less frequently in mumps, whooping-cough, influenza, and enteric fever, and very rarely in the other diseases. Those of the second group may occur in any of the acute infectious diseases. This group comprises such complications as meningitis following otitis media, cerebral embolism after cardiac thrombosis, and so forth.

To them may be added certain affections of the central nervous system which have been observed to arise in connexion with small-pox, varicella, vaccinia, measles, and rubella. Now in respect of these there is one important point to which none of the speakers in the debate appears to have alluded—namely, that they have been noticed to occur more frequently since those two stupendous historical events—the war and the influenza pandemic of 1918-19. It is since those calamities that epidemic encephalitis has also been more frequent. Is there any connexion between the nervous diseases and either the war or the pandemic? I confess to being impressed with the evidence brought forward by Sir William Hamer and the late Dr. Crookshank, which connects both sporadic cases and outbreaks of these nervous diseases with the great epidemics of influenza; and I agree with that opinion, which was referred to in the discussion by Dr. W. Gunn, that there is "a specific virus causing all forms of encephalomyelitis, the infectious disease merely activating this virus, etc." From the epidemiological point of view the whole question is of great interest.

A minor point relates to diagnosis. I admit that I am suspicious of sporadic cases diagnosed as measles or rubella complicated with encephalitis or myelitis. Epidemic encephalitis may be accompanied by a morbilliform eruption. The first case of this form of encephalitis to come under my observation was that of an American officer who was sent to the Grove Military Hospital (of which I was then commanding officer) with the diagnosis of measles at the time when encephalitis was first appearing in this country and was being confused with botulism. Later I saw a similar case in a boy. Psychoses following, and presumably due to an acute infectious disease, are relatively uncommon. In my experience they have been observed most frequently after enteric fever.—I am, etc.,

Hampstead, March 24th

E. W. GOODALL.

Colonic Irrigation

SIR,—I am glad to see in the *Journal* of March 24th a letter from one with the authority of Mr. Wilfrid Adams drawing attention to the risks of colonic irrigation, especially when carried out indiscriminately or by those who are not expert. I hope that there will now be a further communication from some physician of wide experience and open mind telling us whether any harm, less obvious, may be the consequence of this treatment, and whether, if no harm is done, it is often useless or could be replaced by other methods more simple, possibly more effective and less inconvenient, and also less costly to the patient.

I am tempted to write this note because it is evident that colonic irrigation has now become a socially fashionable treatment. Other panaceas of equal notoriety, such as vaccines and the removal of tonsils and of every tooth, appear to be losing their precarious hold of this position, and there seems to be little left but to remove all the contents of the colon and this for all sorts of conditions. During the last year or so patients, within my own knowledge, who have been sent, or gone away, for further advice, suffering from rheumatism, fibrositis, anaemia, gall-stones, disseminated sclerosis, furunculosis, and last, but by no means least, high blood pressure, have all fallen victims to the fascination of this last satellite of fashion.

There is real danger in the vogue, for, though no one will deny the value of this treatment when rightly used, we all know the obloquy that follows the court favourite when he falls out of favour. A patient who consulted me three days ago told me that, for the treatment of so-called fibrositis, she had not only had all sorts of baths and medicaments and electrical treatment, but for thirty days had had on every other day a Plombières douche; she was no better.—I am, etc.,

Bradford-on-Avon, March 26th. CHAS. E. S. FLEMING.

The Milk Question

SIR,—Dr. W. S. Forbes, in his letter of March 24th, raises a number of points which I think cannot be accepted as a correct representation of the facts. As the subject is so large I will confine my remarks to tuberculosis.

He states as significant that in Scotland 2.8 per cent. of pasteurized milks contained living tubercle bacilli. If, however, the details of these positive findings are studied in the appendix it will be found that for none of them do the time-temperature factors correspond to those required for "official" pasteurization. All of us who advocate milk pasteurization as a satisfactory method of obtaining pure milk are insistent as to the need for accurate control of the pasteurization process and for a rigid observance of reliable temperature and time periods. The figures merely emphasize this need, and it is of interest to note that in spite of deviations from them in this series the danger of living tubercle bacilli in milk was reduced by over 90 per cent.

Dr. Forbes goes on to suggest that bovine tuberculosis in man is not necessarily derived from milk infection. Milk of course includes milk products, and I would ask from what other sources can bovine tubercle bacilli infect man? There is general agreement that the amount of infection from tuberculous meat is negligible. The only other source I know of is the possibility of infection from a human case suffering from pulmonary tuberculosis of bovine origin, and in view of the rarity of such cases this factor must also be insignificant.

Dr. Forbes's suggestion that to provide a clean milk supply will largely make it a safe milk supply, as regards

the risk of conveying tuberculosis is in direct contradiction to the very large volume of information we possess on the subject. The "application of conditions and methods which will ensure a clean raw milk" is a highly desirable aim, but by no stretch of imagination can it influence the infection of the milk supply from cows suffering from tuberculosis of the udder. Dr. Forbes's view is obviously based upon a later statement: "I am convinced that the tubercle bacillus enters the milk in the vast majority of cases not directly from an infected animal, but indirectly from contamination with dung, etc." It would be most interesting to have the evidence of this conviction, for all the facts are the other way. The point is important because, of course, if this is true, cleanliness would do what Dr. Forbes claims for it. We know that tubercle bacilli do get into the dung and obviously, therefore, some will get into the milk with gross lack of cleanliness. Our facts, however, show this cannot be more than a small factor in the infection. I can illustrate this best by quoting my experience with milk samples collected in Somerset directly at the farms from the mixed milk of all the cows in milk at the farm.

Taking the figures for the years 1931, 1932, and 1933, in thirty-two instances tubercle bacilli were found in the mixed milk. In twenty-six cases the veterinary surgeon at his first visit (with bacteriological assistance) picked out the infecting cow, while in four other cases the cow was detected after selected bacteriological testing. In all thirty cases the cows on slaughter showed extensive tuberculosis infection, together with definite udder tuberculosis. Of the two other cases, in one two aged cows had been sold between the sampling and examination and one was probably the cause of infection; in the other case a markedly tuberculous cow was found and slaughtered, but no udder disease could be found post mortem.

Considering the technical difficulties, a proportion of 94 per cent. traced directly to a cow with udder tuberculosis shows unmistakably that it is to the cow with a tuberculous udder that we must look for the source of tubercle bacilli in our milk supply. This experience can be paralleled by all who keep records of these investigations. Unless all the cows in a herd are free from tuberculosis and kept free no application of clean milk methods will remove the risk of tubercle bacilli in the milk, and nothing but efficient heat treatment of that milk will make the supply safe.—I am, etc.,

Weston-super-Mare, March 25th.

WILLIAM G. SAVAGE.

SIR.—In his letter on "The Milk Question" (March 24th) Dr. W. S. Forbes rocks on seas of controversy, but touches solid ground on two points. As both provide useful anchorage in a stormy voyage they deserve special charting. The first is noted in the words, "The country districts require the greatest consideration, as it is practically impossible to pasteurize all the milk consumed in them." The second reads: "Here is the opportunity of dealing with the whole question which may never occur again, and it must be grasped." As the Great War provided us with that remarkable by-product "daylight saving," so may the threatened devastation of the dairy industry supply the unexpected boon of cleaner and safer milk. Such chance for Government aid may truly "never occur again," but unless the medical profession shows itself as alert and united as the agricultural interests, the children's milk ration will be of very doubtful quality. How, indeed, can it be "pure" under existing conditions? If the Ministry of Agriculture looks out for "cleanliness" the Ministry of Health must be supported by the doctors when it demands "safety," as well. The country school must be its milk.—I am, etc.,

Perth and Kinross, March 25th.

ESTHER CARLSON.

SIR.—Last November my council instructed me to take a sample of milk from each cow-keeper and send it to the School of Agriculture, Cambridge, for examination every quarter. The following figures may be of interest to your readers as showing what can be done:

Sample	November, 1933		March, 1934	
	Count	Coli	Count	Coli
A	48,000	1,100	35,200	170
B	163,000	1,190	6,500	Absent
C	68,000	1 c.c.m.	141,000	1 c.c.m.
D	27,200	170	5,600	Absent
E	65,000	1,100	127,000	"
F	96,000	1,100	92,000	17,000
G	81,000	17,000	127,000	17,000
H	81,000	Absent	48,000	Absent
I	60,000	17,000	191,000	"
J	32,000	1,100	3,500	"

—I am, etc.,

St. Neots, Hants, March 25th.

E. J. CROSS.

SIR.—Dr. W. S. Forbes's letter in the *Journal* of March 24th in a very able way seeks to sum up the situation. Pasteurization *per se* is probably the best way of supplying cities with milk under present conditions. Dr. Forbes deals with epidemics, and points out that evidence from milk is misleading, because diseases come from so many sources. Air-borne germs are difficult to control. Advocates of raw milk are concerned with vitamins, and possibly something more elusive (what it is may some day be discovered), which they claim are destroyed by heat.

It is interesting to note that the child on raw milk is very fit, that chilblains are practically eliminated, and that Dr. E. Sprawson has shown that teeth are less likely to decay owing to better dentine formation. Our experience, through a succession of years, shows that tubercle is not the result of drinking raw milk.—I am, etc.,

A. H. MACDONALD,

Stonewy Causeway, E.L.I. Chief Medical Officer, Dr. Barnard's

Hypochondriasis

SIR.—Dr. F. Gray's letter in your issue of March 24th (p. 558) raises questions which are of the utmost importance when we come to consider the limits of analytical psychotherapy. The neglect to respect these limits is responsible for much of the odium which has been cast on treatment based on analytical investigation.

It is a little difficult to deal critically with Dr. Gray's letter, as he has mixed the categories which were so clearly defined in Dr. Hutchison's article; but I should like to emphasize the danger and the uselessness of attempting any radical cure in the latter's "general hypochondriac." Has Dr. Gray really ever told a retired colonel that his abdominal discomforts were due to a wish that he had been a general, coupled with his failure in that respect? If he has I trust that he will patch the case in full, with the colonel's replies and reactions. It will hardly have been possible for the colonel to arrive at the conclusion through any analytical procedure, for patients of this age and temperament are usually not analysable, and if they are the results are apt to be disastrous.

Not every elderly hypochondriac, however, has been given a relative failure in life. Many successful people

who have retired from active business life because they were tired of it develop hypochondriacal symptoms, and one patient whom I had under observation for many years had not retired at all, but was in busy practice as an accountant. More than once he sent for me to come to his house to inspect his urine, which had to be left undisturbed in the chamber-pot, so that I might see a curious film on its surface. At another time he wanted me to drive five miles into the country to inspect a series of stools of his, which he had arranged behind a hedge, and of which he did not like the colour. I have tried in the past to effect radical cure on these patients, and am convinced that the only therapy desirable or possible for them is that outlined by Dr. Hutchison, the psychotherapy which consists in giving the patient the feeling that he is being taken care of. The nosophobe is in a different category. I am sure that Dr. Hutchison is right in saying that many of them have been created by health propaganda, or by doctors giving unjustified hints about blood pressure and so forth. Patient explanation on the conscious level will relieve a considerable number. In others, as Dr. Gray suggests, the phobia is a cover for unconscious difficulties, and in these an analytical procedure may be very successful: I have published such a case in detail. There are, however, other examples where the phobia is a cover for a psychosis, and such must be approached with the utmost caution.

With regard to the vicarious hypochondriacs, I believe it is true that there is in most of them an unconscious factor of importance, the release of which would be beneficial, though I should doubt that this factor was necessarily connected with inferiority or insecurity. Surely there are guilt factors of all kinds—death wishes, incest wishes, and others—which cannot be subsumed under the general term of "inferiority." Now the difficulty here is that the patients feel quite well, and therefore will not submit to treatment. Why should they? Their anxiety seems to them proper and laudable; they will not enter a treatment which avowedly aims at removing their virtuous thoughts and acts. And if they did agree to be treated, it is well to note that analysts of all schools are at one in holding that the analysis of people who feel well is more difficult and lengthy than that of those who admit to illness. The old father will be dead, and little Philip will be a man, before the help which the analysis of the other person is to afford will be available. But much can be done on the conscious level to re-educate the vicarious hypochondriac, and it is really Dr. Gray and not Dr. Hutchison who is the pessimist here.

It is in the region of the compensation neuroses that the influence of environmental action in the creation of these disorders is most easily seen. If there were no compensation for accidents there would be no traumatic neuroses. The proofs of this have been given so frequently that they need not be repeated now. But as this is true for these special disorders it cannot be false that publicity and propaganda and any other morbid suggestion must have some effect in the genesis of neurotic illness. As a practical proposition we cannot have an analysis carried out on the whole population, and therefore it behoves us to do what we can to inculcate mental public health on the conscious layer. Freud has helped us beyond measure by his insistence on the importance of the unconscious in influencing our thoughts and actions; but he did not thereby abolish the importance of consciousness, which, after all, has a considerable influence on what we do and think.—I am, etc.,

Hypochondriasis, Labour, and Analgesia

SIR,—It is disappointing that Drs. John Elam and R. J. Minnitt (*Journal*, March 24th, p. 559) have paid so much attention to personalities rather than exercise a little logic on the principal question at issue. It was open to either, in advancing the claims of his pet form of analgesia in labour, to counter-argue that the knowledge of the existence and practice of a perfect form of analgesia would be a factor in helping women to secure an equable frame of mind before entering labour. Neither has taken the opportunity. Instead, Dr. Elam offers facts either which are so rudimentary as to come within the knowledge of third-year undergraduates, or which have no bearing on the point whatever. Dr. Elam, if paternal, writes in friendly fashion, which I appreciate. It is otherwise with Dr. Minnitt, who seems to be in bad taste by casting thinly veiled aspersions on national learning and personal character.

In any case, Sir, I maintain that neither Dr. Elam nor Dr. Minnitt has contributed anything to a discussion on whether the profession is, by its methods, helping or hindering the presence of a desirable mental attitude in a woman towards her approaching labour. I thank you, Sir, for the courtesy of your columns, upon which I shall not trespass further.—I am, etc.,

Kilnarnock, March 27th.

JAMES W. HAMILTON.

* * We cannot publish further letters on this side-issue of Dr. Hutchison's lecture.—Ed., *B.M.J.*

Maternal Mortality in Maoris

SIR,—With reference to Dr. Kathleen Vaughan's letter in the *Journal* of November 18th, 1933, I am afraid that, in relying upon Mr. Elsdon Best's statement, she is relying upon conclusions derived from a too limited knowledge of obstetric conditions and results among the Maoris to allow of such conclusions being regarded as reliable. From what I have read it appears that Mr. Best drew his conclusions from one or two cases of remarkably easy labour with which he was acquainted. I think it would probably be more accurate if, instead of saying that "Maori folk did not die in childbirth," which is obviously a gross misstatement, he had said "the average Maori woman with normal labour had a more easy time than the European woman"; and I think we can conclude that their active life, their less civilized condition, possibly the squatting position generally adopted by them, and their walking bare-footed, with their peculiar rolling motion of the hips, were the principal causes. This, however, is, more or less, surmise. What is positively known is that:

1. The majority of Maoris still habitually use the squatting position during meals, during rest otherwise than in bed, during defaecation, and during parturition.
2. The maternal mortality of the Maoris who do not adopt European obstetric methods is approximately double that of Europeans.
3. The high maternal mortality is chiefly attributable to accidents of labour and sepsis following childbirth, septic abortion having a very minor influence on the death rate. We are also sure that sepsis in the Maori is not due to vaginal examinations or internal manipulations, which are practically never made, and that many of these cases of sepsis are due to retained placentas. Septic sores are common among the Maoris, and from these infection is probably conveyed to the lying-in woman by the Maori attendants on their hands or on the clothes used.

I quote the following deaths from puerperal sepsis following retained placentas: placenta retained for three

days, fourteen days, eighteen days, "till death occurred," "several days." Another unduly frequent cause of death is from shock, haemorrhage, etc., due to obstructed labour. Taking twenty-nine consecutive cases of death, as reported by the Health Department's nurses attending or inquiring into these cases (they are so often called in too late), I find the following recorded: childbirth incomplete, two days; childbirth, two to three days; childbirth, four days; obstructed labour, three and a half days; obstructed labour (shoulder presentation), four days; ruptured uterus; and of the remaining cases nine deaths were from puerperal sepsis. I think it is safe to conclude that the only means of saving the above cases of obstructed labour was the use of better obstetric methods.

It may interest Dr. Vaughan to know that the Maori method of "helping" the woman in such cases is by external pressure. This is usually applied by a powerful man, who may squat in front of the seated woman and, with all his available power, press the abdomen against his shins and knees. I know of one ruptured uterus occurring in this way. Another method is by winding a thick rope tightly around the woman's body. In the above circumstances one cannot be surprised that the maternal mortality of the Maori is higher than that of the European.

Regarding the teeth, the impression one gets from general observation would lead one to suppose that the Maori generally has wonderful teeth, but accurate observation shows that among school children there is now considerable deterioration in the teeth, due to caries, the incidence of which, in the Maori school child in many districts, is higher than in the European. It is an axiom of the health workers among Maoris (school medical officers and nurses) that the nearer a Maori lives to a store the worse will the children's teeth be. I think it is safe to conclude that this deterioration in the teeth of the Maori is due to adoption of the dietetic habits of the Europeans and abandonment of the native diet customs and the native methods of cooking.—I am, etc.,

Department of Health, Wellington,
New Zealand, Feb. 15th.

T. L. PAGET.

Cerebral Oedema

SIR,—With reference to Dr. F. A. Belam's case (March 24th, p. 531) headed "A Very Rare Cause of Sudden Death," acute cerebral oedema is, of course, not an uncommon mode of dying, though rarely, in my experience, compatible with terminal consciousness. As for the cause behind it, though the kidneys are said to be normal, it would be interesting to know (a) whether there was any urine, and, if so, what was found in it; and (b) what was the urea content of the cerebro-spinal fluid.

Dr. Belam does not say what organism was found in the nasal and aural discharges or in the glands in the neck. I am thinking in particular of the Klebs-Loeffler bacillus. In a fatal case of nasal diphtheria examined by me quite recently (showing also a right adenitis) I found in the neck abscess abundant diphtheria bacilli.—I am, etc.,

The Princess Alexandra Hospital,
For Scotland, Glasgow, 1934.

THOMAS GRY.

Acute Thyroiditis following Teeth Extraction

SIR,—Mr. R. H. Paramore, in his letter in the *Journal* of March 24th (p. 538), seems entirely to have overlooked the fact, which I thought I had made abundantly clear, that the case which I describe in your issue of March 10th (p. 428) presented symptoms—namely, rapid onset of acute pyrexia, toxic swelling, and elevated temperature—which in my opinion could only be pointed to as a definite inflammatory process affecting the whole of the thyroid

gland: in other words, an acute thyroiditis, a rare but well-recognized clinical entity. That it was due to infection with pyogenic bacteria was, in the circumstances, reasonably certain, only lacking final proof in that, happily, the inflammation settled without suppuration.

What parallel is there, then, between my case and that which Mr. Paramore describes? His case was apparently one of Graves's disease, of six or seven months' duration; my case had no symptoms of thyroid intoxication, only symptoms of septic absorption, which disappeared in a few days with resolution of the inflammation. His later remarks about the misuse of the term "infection" with regard to disease in general seem, therefore, most inaptly applied to the case which I have described.—I am, etc.,

Glasgow, March 26th.

IAN B. THORBURN, F.R.C.S. Ed.

Chilblains

SIR,—Surely Dr. G. C. Gillison's paraphrase of the story of Naaman, in his letter to the *Journal* of March 24th (p. 560), misinterprets the original, in which Naaman was the patient and not the physician.

May I suggest several reasons why the modern Naaman should prefer the Abana and Pharpar of thyroid to the Jordan of passive congestion? Thyroid tablets, taken as they ought to be in the morning and at midday—not at night, because of their possible cardiac or metabolic disturbance—provide a simple and effective remedy, and savour less of symptomatic treatment of a condition which is, after all, a manifestation of metabolic inadequacy. Anyone who has attempted to bandage his right wrist must appreciate the difficulty of the operation, efficacious though it may be. Chilblains frequently occur on the feet, and may thereby render somewhat cumbersome the second part of the "congestion" treatment—namely, raising the limb "above the head for a minute or two."—I am, etc.,

W. MUNRO LITTLE, M.B.

Feltham, Middlesex, March 26th.

* * This correspondence is now closed.—Ed., B.M.J.

Blood Pressure and Decubitus

SIR,—Dr. Barclay Dickson's observation, as reported in your columns of March 24th (p. 534), that the blood pressure in the later months of pregnancy, the patient lying on her back, is appreciably higher than when she is lying on her side, and that a similar difference occurs in non-pregnant people, is in line with my observation, published in 1913, that the pressure in the rectum, with the patient on the back, is appreciably greater than when in the lateral position. The evidence is that these two sets of phenomena are correlated—the pressure in the artery depending on the pressure in the abdomen.

Dr. Dickson, however, thinking the visceral weight the only force to reckon with in the abdomen, and that it is only operative in the dorsal decubitus, attributes the greater blood pressure when on the back to this factor: the viscera, in virtue of their weight, stimulate the sympathetic plexus, causing an increased constriction of the visceral arterioles. But the peripheral resistance beyond the arterioles rests only in the abdomen, long disordered, that presented by the pressure of its capillaries, caused by the cells, capable of extreme swelling, contained in it. It is also to be considered as a factor diminishing the arterial blood pressure. Moreover, one must remember that the amount of blood returned per unit time to the heart, especially in the supine position, is considerably related to the volume of the venous system, and thus to the blood pressure. That both these pressure factors in the dorsal decubitus than in the lateral position are indicated by my research.

Recently, with a new manometer, I have been measuring the pressure in the rectum and in the stomach of non-pregnant women, of women late in pregnancy, and in some after delivery. The fluid used has a specific gravity of 1050—approximately that of blood. To date, I have made forty-three observations with this new machine. Here are a few pertinent findings.

Case Number	Age, Height, and Weight	Condition	Pressure in Rectum in cm. of Fluid— Specific Gravity 1050	
			Left Lateral	Back
19	35 years; 4 ft. 10½ in.	Primigravida; near term. (Labour thirteen days later)	13/75	30/31
27	23 years; unmarried	Primigravida; six months pregnant. Denied pregnancy	15	33
37	Same case; two months later: 5 ft. 3½ in.; 9 st. 6 lb.	Now married. Eight months pregnant	18	35
43	25 years; 5 ft. 3½ in.; 9 st. 12 lb.	Multipara. Three or four previous pregnancies. Over eight months pregnant. Weak muscles; delicate build	19	16/77
24	18 years; 5 ft. 4 in.; 10 st. 7 lb.	Nullipara; fine specimen. Dysmenorrhoea (Stomach tube also passed)	6/7	20/21
25	Same case; seven days later		8/9	23

In two of these cases, the patient being on the back, note was made as to the height of the fluid in the manometer and the highest point of the patient's abdomen. In No. 27 the fluid column was sustained 12 cm. above the highest point of the abdomen; and in No. 19 it was sustained 9 cm. above that level.

Such readings put out of court the idea that gravity—the weight of the viscera—is the cause of the pressures: they indicate that the state of the abdominal wall muscles is much more important. That the compression these muscles produce, by its effect on the blood streaming through the abdomen, is a vital force, influencing general metabolism and playing a part when exaggerated in the occurrence of pathological processes, is shown by many considerations. Dr. Dickson's observation—that the blood pressure is greater when on the back than when on the side—affords, in my view, direct evidence of the former; and he is to be congratulated on having made a discovery of the first importance.—I am, etc.,

R. H. PARAMORE, F.R.C.S.

Rugby, March 25th.

Cost of L.C.C. Hospitals

SIR,—In the annotation on the "Cost of London Health Services" in your issue dated March 31st (p. 589), it is stated that the vote for maintenance expenditure for the general hospitals (L.C.C.) was put down at £469,000. This figure is taken from the Report of the Finance Committee to the London County Council, dated March 23rd, 1934, and is an estimate of the probable expenditure to be incurred by the Council on capital and on maintenance accounts under the headings of "Hospitals and Medical Services Committee" and "General Hospitals." This figure is an estimate for the ensuing financial year 1934-5. I would like to point out that this estimate is for two months' expenditure only, and that the maintenance of the L.C.C. general hospitals does not cost £469,000 per annum, but six times this amount.—I am, etc.,

London, N.W.1, March 30th.

GEOFFREY EVANS.

* We regret the misapprehension pointed out by Dr. Evans. We understand, however, that the expenditure for the full year cannot be ascertained by multiplying the figures by six, because the incidence of certain items of expenditure is spread unevenly over the twelve months. For example, the £57,000 for the venereal diseases scheme represents half the annual expenditure.—ED. B.M.J.

Obituary

DAVID LEES, D.S.O., M.A., M.B.,
F.R.C.S.Ed., F.R.C.P.Ed., D.P.H.

The death took place on March 25th, after a short illness following an operation, of Dr. David Lees, who was clinical medical officer under the Edinburgh Public Health Department, and head of the department for venereal diseases in the Royal Infirmary of Edinburgh. He was an outstanding figure in public and medical circles of Edinburgh, and was one of the leading authorities in Britain upon venereal disease.

David Lees was born in 1881, the son of Mr. Robert Lees, M.R.C.V.S., of Lagg, Ayrshire, a well-known agriculturist. After preliminary education at Ayr Academy he studied medicine at the University of Edinburgh, where he graduated M.B., Ch.B. in 1907. Following a period as resident surgeon in the Royal Infirmary of Edinburgh with the late Dr. Freeland Barbour, then university lecturer upon gynaecology, he acted as resident in the Royal Maternity Hospital, Edinburgh, and house-physician at Bangour Mental Hospital. Thereafter for some years he engaged in general practice in the North of England. On the outbreak of war he joined the Royal Army Medical Corps as a temporary captain, and served until 1919. In France he was awarded the D.S.O. for conspicuous gallantry.

While attached to the Guards Brigade he went out to "No Man's Land" under heavy fire, attended to a number of wounded men, and brought them back without assistance.

Towards the end of the war he took the special course on venereal disease provided by the R.A.M.C., and became specialist in this subject at Brighton Grove Military Hospital, Newcastle, and at Robroyston Military Hospital, Glasgow. Becoming a recognized authority upon this subject, he was appointed, after the war, adviser on venereal disease to the Derbyshire County Council, and a short time later joined the staff of the Edinburgh Public Health Department as the first specialist in venereal disease to be appointed by the Edinburgh Corporation. At the same time he was placed in charge of the department for venereal disease established at Edinburgh Royal Infirmary, and was appointed lecturer upon this subject in Edinburgh University. The great development which took place in these departments and the advances in treatment which originated there were due to his energy and influence. His eminence in this branch of medical science and treatment was universally recognized, and was manifested by the frequency with which he was consulted regarding the initiation and development of similar departments in other places. It was also evidenced by his appointment as chairman of the Medical Advisory Board of the British Social Hygiene Council, and as president of the Medical Society for the Study of Venereal Diseases in London. In these posts he wielded an important influence in the extension of their work, not only in this country but throughout the Empire, being frequently called into consultation by Government departments. During 1926-7, on the invitation of the Provisional Governments, he made a tour of India and Burma in order to lecture and advise them on problems connected with venereal disease.

David Lees had joined the Royal College of Surgeons in Edinburgh as a Fellow in 1918, and in 1928 he took the Membership of the Royal College of Physicians, proceeding to the Fellowship of the latter body in 1931. In 1930 he took the Diploma of Public Health at Edinburgh. He was the author of a well-known textbook on *Practical Methods in Diagnosis and Treatment of Venereal Disease*, which attained a great measure of success and went into a second edition in 1931. He also found time for various communications to current medical literature, such as articles on "Locomotor Ataxia" and "Vesiculae Seminales," in the *Encyclopaedia Medica* in 1924; "Clinical Treatment of Gonococcal Infection," in Thomson's *Gonorrhoea* (1923); and "Keratoderma Blenorhagica," in the *Edinburgh Medical Journal* (1922). He was an interesting and vivid lecturer, and his demonstrations to students and to meetings of medical practitioners were always eagerly attended. An important figure in the administration of medical affairs, both in Edinburgh and in a wider circle, had been confidently predicted for him, and his death comes as a great loss to the medical profession. He took a keen interest in the British Medical Association, serving upon its Representative Body from 1928 to 1933, and upon several of its central committees, and his breezy personality, high qualifications, and judicious counsel were greatly valued in the deliberations of the Association. He was elected vice-president of the Section of Venereal Disease meeting in 1923 at Portsmouth, and president of that Section in 1927 at Edinburgh.

His kindly manner, ready humour, and dynamic energy in administration earned for him both the affection and the respect of his colleagues, and his presence will be greatly missed in the Edinburgh medical circles where he was best known. He is survived by a widow and one son. The interment took place in the Grange Cemetery, Edinburgh, on March 28th, and was attended by a large number of members of the medical profession, and by representatives from various public bodies with which he had been associated.

ARTHUR LYNCH, M.A., M.R.C.S.

The career of Colonel Arthur Lynch, who died in London on March 25th, was so varied and full of adventure with sword and pen that the fact that he was a medical man and had a general practice in North-West London for some years might well escape notice.

Arthur Alfred Lynch was born at Ballarat, Victoria, rather more than seventy years ago, and was educated at Melbourne University. For a time he practised in Melbourne as a civil engineer, and then made his way to Europe, studying in Berlin and in Paris, where he took a diploma in electrical engineering. From his Irish father—his mother was Scottish—he inherited a fervid patriotism, which, with his poetical and ardent mind, explains much in his subsequent history. In the stormy years of Irish politics, when Parnell was still in the ascendant, Lynch identified himself with Irish Nationalism, and sought, unsuccessfully, to enter Parliament for an Irish constituency. He resigned his political aspirations for a time to become the Paris correspondent of a London newspaper, but when the South African War was declared he threw up this post to go out and fight for the Boers. He commanded an Irish brigade under General Botha, and took part gallantly in some engagements against British troops. Towards the end of the war he was returned to Parliament as member for Galway City, and in a somewhat flamboyant letter to the Speaker of the House of Commons announced his intention of resigning his seat, and appealed for an oblivion of the past. On disembarking at Newhaven he was arrested, and in

due course was tried before three judges for treason, found guilty, and sentenced to death. The sentence was immediately commuted to imprisonment for life, and at the end of a year—according to his own story, at King Edward's personal intervention—he was released. In 1907 he was granted, by the new Liberal Government, a free pardon. His thoughts next turned to a medical career, for which he studied at St. Mary's Hospital Medical School in London and at the Hôpital Beaujon in Paris. He qualified when 37 years of age, and, having also been returned as a Nationalist member for West Clare, he settled down in London as physician and surgeon and as a Member of Parliament, which latter he remained until the Nationalist Party was swept aside by Sinn Féin. He was for some years a member of the British Medical Association.

During the Great War Lynch gave whole-hearted support to the Allied cause. Up to this time, in any reference to him in the Press, his rank of "colonel" appeared between quotation marks, but these were dropped when he became actually colonel of the 10th Munster Fusiliers, and was sent to Ireland to assist recruiting. He did excellent service there, although his achievements were far below his own expectations, as he found an Ireland quite different from that which had enlisted the eager sympathies of his young manhood.

In the field of literature Arthur Lynch was equally versatile. His output took the form of sonnets, biography (including an account of his own adventurous life), philosophical essays, and fiction. His most ambitious work—*Psychology: A New System*—was published in 1912, and was described as "based on the study of the fundamental processes of the human mind." This was followed, in 1920, by *Principles of Psychology*, a work later translated into French. His last achievement was *The Case Against Einstein*, in which he devoted 300 pages to the confutation of that philosopher.

Dr. F. W. EDRIIDGE-GREEN writes: As a very intimate friend of the late Colonel Arthur Lynch I should like to pay a tribute to his extraordinary intelligence. Like the late Lord Moulton, he had the power of immediately detecting the weak point in an argument. Again and again during the war, when a point of action was under consideration, he gave me the solution, which was afterwards adopted or pointed out in some book after the war as the correct procedure. It is easy to solve a problem when you have looked at the answer. In addition to his other accomplishments he was a mathematician of a very high order. On one occasion he sent a mathematical paper to a society and it was rejected. I took the trouble to try to find out why, and asked a very able man the reason. His reply was: "There was no one who could understand it." A very common but very silly reason for rejecting a paper. His two books, *Science Leading and Misleading* and *The Case Against Einstein*, are two splendid examples of his critical faculty.

Dr. SAMUEL LODGE, who died on March 19th at his residence in Harrogate at the age of 68, had been for many years a prominent figure in Bradford. He received his medical education at Durham, Leeds, and St. Thomas's Hospital, graduating M.B., B.S. Durh. in 1887. He proceeded M.D. two years later. After holding the appointments of resident medical officer to the Dunston Asylum, Durham, resident medical and resident surgical assistant to the Royal Infirmary at Newcastle-on-Tyne, and working at the Pasteur Institute, Paris, he commenced general practice in Bradford. For several years he held the appointment of senior assistant surgeon to the Royal Eye and Ear Hospital, Bradford, after resigning which he became ophthalmic and aural surgeon to the Royal Halifax Infirmary, being appointed consulting surgeon in 1924. He had devoted many years' service to the Territorial Army, and received the T.D. During the

first part of the war he held a commission in the 6th Battalion of the West Yorkshire Regiment. Later he was in charge of medical boards at Leeds and Bradford, and was awarded the O.B.E. He retired from the R.A.M.C. with the rank of major. Dr. Lodge was the author of several articles on eye conditions in the *British Medical Journal*. His eldest son, who died last year, was ophthalmic surgeon to the General Infirmary at Leeds. Three of the four surviving sons are in medical practice, one having succeeded his father in 1924 as surgeon to the ophthalmic and aural departments of the Royal Halifax Infirmary.

We regret to record the death of Dr. GORDON CALTHROP on February 20th. Dr. Calthrop was born on July 18th, 1867, and received his education at Felsted and Cambridge, where he graduated M.B., B.Ch., in 1891. He held house appointments at the London Hospital, where he completed his medical education, and at the Royal Northern Hospital, Holloway. He then went to Cross Hills (Yorks), where he lived for some years, before moving to Wells (Norfolk), in which town he practised for thirty years, retiring at the age of 65 in July, 1932. Dr. Calthrop was in no small measure responsible for the successful organization of the Wells and District Cottage Hospital, which was established in 1910. He also took a great interest in the town's affairs. Among his medical appointments were those of medical officer of health for the town and port of Wells and medical officer to the Wells and District Cottage Hospital. Dr. Calthrop had been a member of the British Medical Association for thirty-seven years.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

In the House of Lords, on March 27th, the Betting and Lotteries Bill was read a first time. It contains provisions to penalize traffic in foreign lottery tickets and counterfoils. The Marriage (Extension of Hours) Bill was read a second time, and the Shops Bill passed through report. On March 28th the Plymouth Hospitals Amalgamation Bill was read a second time. The Birmingham United Hospitals Bill and the Shops Bill were read a third time. The Royal Assent was signified to the Dyestuffs Import Regulations Act, Rural Water Supplies Act, Indian Pay (Temporary Abatements) Act, and Mining Industry (Welfare Fund) Act.

In the House of Commons, on March 28th, the Birmingham United Hospitals Bill was read a first time, and the Coal Mines Bill a second time. A Protection of Animals (Cruelty to Dogs) (Scotland) Bill was presented in the House of Commons on March 29th by Colonel Moore, supported by Dr. Hunter. Its purpose is "to enable courts in Scotland to disqualify from keeping dogs persons convicted of cruelty to them."

The House of Commons will resume on April 9th. The second reading of the Road Traffic Bill is set down for April 10th. The House of Lords will resume on April 11th.

The final revenue returns for 1933-4 show that the financial year closed on March 31st with a surplus of £31,147,000. The Budget will be presented on April 17th. In answer to a request that the Parliamentary Medical Committee should have an opportunity to make representations about the "cut" in the remuneration of insurance medical practitioners, the Chancellor of the Exchequer has intimated that this matter should be brought before the Minister of Health.

Slum Clearance: Lords' Debate

In the House of Lords on March 21st the ARCHBISHOP OF CANTERBURY moved a resolution welcoming the Government's proposals for slum clearance and against overcrowding, and hoping for early and effective operation of these measures.

He said that clearance of the slums, the provision of houses at rents which could be paid by the lower-waged workers, and the evils of overcrowding remained practically untouched, despite all the housing activity since the war. In London 150,130 persons lived three or more in a room. In fifteen cities more than 500,000 persons lived more than three in a room, but not all of these lived in slums. Lord BALFOUR OF BURLEIGH said not fewer than 1,000,000 houses were needed to remedy the housing deficiencies of the country.

VISCOUNT GAGE, for the Government, said an essential condition of the slum clearance scheme was that effective action should be taken to prevent overcrowding of the new dwellings. The initiation of the slum campaign had had definite effect in inducing property owners to remedy housing defects. No figure could be given, but the Government estimated that houses thus improved were far in excess of the quarter of a million houses affected by the slum programme.

THE BISHOP OF WINCHESTER said that two-thirds of the families in London shared a house with one or two other families. In 1921 there were 137,000 more families not in possession of a separate dwelling than at the census of 1911; and at the last census there were 75,000 more families, in addition to the increase on the last occasion, which did not possess separate houses. Intense overcrowding—three or more to a room—increased by 45,000 in the last ten years. The L.C.C. and the local authorities had done a great deal in the past in providing splendid estates, but they had failed so far to deal with the poorest members of the community. While Birmingham and Liverpool built respectively 76 and 67 per cent. in proportion to the increase in population, London had only built 24 per cent. Lord LISTOWEL said that, accepting as a minimum standard of housing accommodation the standard approved by the Minister of Health, they discovered there were approximately 4,000,000 houses that did not satisfy the minimum requirements. Lord HALIFAX said that during the sixteen years since the war well over 2,000,000 houses had been built for a cost put at £450,000,000, while the population had only increased by some 2,000,000. As Minister of Education he had an illustration placed before him not long ago of the effect of slum life upon children in the schools. Out of 100 children from the slums compared with 100 children from better homes, not fewer than sixty-four slum children were below the standard, as against eleven of the others; thirty-four poorly nourished, as against nine of the others; and at the age of 11 only three slum children had reached a class attained at the same age by thirty-seven of the children from better homes.

The House agreed to the Archbishop's motion.

On March 22nd, in the House of Lords, Lord MOYNE opened a debate on the density of houses in the planned area of Greater London. VISCOUNT GAGE said a standard average housing density of twelve to the acre did not mean that every house must have one-twelfth of an acre. The Minister of Health would always consider proposals for a higher density of building, but any proposal for building in a town planning area must be covered by a density schedule. Over 200,000 acres of vacant land suitable for building existed within fifteen miles of Charing Cross, and 7,200 acres of undeveloped land in that radius had been zoned at more than twelve houses to the acre.

Care of the Poor in Scotland

In the House of Commons on March 27th Mr. SKELTON moved the second reading of the Poor Law (Scotland) Bill. He said that the Bill was an indispensable step to a full and comprehensive modern Poor Law statute. Clause 4 provided that a local authority should, if required by the Department, provide suitable and separate poorhouse accommodation for each or any of such classes of inmate as might be prescribed by regulations made by the Department. At present the Department of Health for Scotland had no power to stimulate local authorities to proceed with the work of improving the poorhouses. Clause 9 provided for the removal, under full and proper safeguards, to a suitable hospital or other institution, of aged and infirm, or physically incapacitated persons who were unable to devote to themselves or to obtain from other persons proper care and attention. The procedure would be that, on a certificate by a medical officer, application might be made by the relieving authority to the

sheriff, who would have to be satisfied that there was a suitable institution to which the person could go. An order, which in no case lasted for more than three months, could then be made for the removal. Clause 10 gave a new right to the poor of Scotland—namely, that the first 5s. of friendly society sick pay should be disregarded in the assessment of their relief. It also incorporated a provision which the Scottish poor had enjoyed up to now—namely, that the first 7s. 6d. of national health insurance benefit should be disregarded. It was provided that a casual poor person should not be entitled to discharge himself from a poorhouse before 9 a.m. of the second day following admission. It was important that when a vagrant or casual poor person was in an institution the opportunity should be taken to cleanse him and his clothing.

Mr. C. MILNE said Scottish Poor Law authorities carried out their difficult duties with zeal, efficiency, and humanity, but had not always the accommodation necessary for detention. The first thing to do was to provide suitable accommodation. Mr. BUCHANAN said that the power to remove old people was capable of the worst abuses, and should be deleted from the Bill. At present, generally speaking, such old people went to the public hospitals.

The Bill was read a second time, and sent to a standing committee.

Silicosis Problems

On March 29th Mr. DAVID GRENELL opened a discussion about silicosis. He said that in 1925 he had cited a number of cases to the Mines Department, which held an inquiry. The report was made to that Department in October, 1929, by Dr. Pirow, who now occupied a high position with the South African Government. Dr. Pirow confirmed the belief that silicosis in the United Kingdom was identifiable with miners' phthisis in South Africa. In February, 1929, a Home Office regulation appeared acknowledging the liability of employers to pay compensation for silicosis. Mr. Grenell added that since then he had often indicated the dissatisfaction of the miners with the conditions under which compensation was payable. Silicosis was spreading in the mining industry. Twelve or fifteen years ago cases had been correlated with the operation of boring machines in the rock of coal mines. A short time ago the Secretary for Mines had reported that in a certain period 400 people had been certified as so disabled by silicosis in the mines of the United Kingdom as readily to obtain compensation. Mr. Grenell believed that was only a small part of the incidence of the disease. He asked the Home Secretary to pursue and expedite inquiries which were being made by the medical staff of his Department, in collaboration with a medical man appointed by the Mines Department. Miners' representatives were convinced that silica was not the only mineral responsible for "silicosis." Experts reported—and the report was consistent with miners' experience—that sericite was present in siliceous rocks, and played a large part in producing this disease. He asked for that to be specially and quickly investigated, because in some districts of the British coalfields there was no stone which did not produce silicosis cases, whereas other districts had not the same incidence. Figures given by the Inspector of Mines showed that of 424 cases in Great Britain 386 were certified in South Wales—80 per cent. of the cases in 25 per cent. of the mining population. In certain parts of South Wales the incidence was still higher, and could not be explained by varying degrees of contamination with silica. Therefore the investigation of sericite as a cause of this disease should be carried further, and other causes should be observed. The regulations laid down that when compressed air was turned on in a pneumatic drill water must be turned on at the same time and the dust laid at the point where it was made. No effective dust-trap had yet been invented, and the miners' leaders in the United Kingdom were not satisfied that an effective and portable respirator was available. Mr. Grenell believed the Secretary of Mines could by Order prescribe wet drilling wherever drilling was done. Miners' leaders would also like research pursued into the effects of the transplanting of the stone dust which was laid, as prescribed by regulations, to prevent the spread of explosion caused by gas.

Mr. DAVID DAVIES said that to secure compensation a man who became disabled had to prove he had been working

on rocks containing 50 per cent. of pure silica. This was exceedingly difficult to prove. Even with wet drilling men would suffer from silicosis. In the unloading process a man was compelled to inhale dust, and when old roads underground were filled the atmosphere was charged with it. To every ounce of coal dust on the roads an ounce of stone dust must be added. A man had constantly to inhale that dust when passing along the main airway, where the velocity of the air was high and where horses and "journeys" raised the dust. Stone dust used on the roads should be sampled much more often to ensure that it was free from silica.

Sir JOHN GILMOUR said that while much could be said for using water with drills or to lay dust the evidence for it was not conclusive. Special measures against silicosis had been brought into force for the refractory industries and for certain processes in the pottery industry. Work was only on the fringe of the problem as yet, but scientists were engaged with a common purpose and all possible expedition to improve matters. A mask or respirator would shortly be available for trial, but an educative process would be needed to ensure its use. Sericite had been found in certain cases to have deleterious effects, but no case had been established against it in which silica was not also present. Sericite, therefore, might be a contributory cause of the disease, but not a primary cause. The Minister of Mines would investigate why the trouble was largely confined to an area in South Wales. Better ventilation in the mines must be of immense importance, and the methods of limiting explosions were being investigated from all practical aspects. At present the Government was in communication with the mine owners on silicosis, and was also ready to accept representations from the Miners' Federation.

Small-pox Outbreak at Nottingham.—On March 20th Sir HILTON YOUNG told Mr. Groves that twenty-five cases of small-pox had been notified in the recent outbreak at Blackburn. Of these, eleven were unvaccinated; their ages were 1 month, and 4½, 7, 8, 16, 19, 24, 25, 27, 30, and 44 years respectively. Twelve had been vaccinated in infancy only; their ages were 22, 31, 33, 41, 43, 49, 55, 56, 59, 61, 62, and 64 years respectively. Two, both 38 years of age, stated that they had been revaccinated in 1917 and 1929 respectively; the former showed evidence of revaccination, but the latter did not. There were four deaths—three of unvaccinated persons, aged 7, 8, and 24 years respectively, and the other of a man aged 62, who had been vaccinated in infancy only.

Local Authorities without Slums.—Replying to Mr. Temple Morris, on March 22nd, Sir HILTON YOUNG said that the local authorities of four county boroughs, seven non-county boroughs and urban districts with a population of 50,000 and over, twenty-two other non-county boroughs, 157 urban districts, and 110 rural districts had reported that no slums existed in their areas. These returns had been accepted by his Department as correct.

Condition of a Mortuary.—Sir HILTON YOUNG told Mr. Thorpe, on March 22nd, that his attention had been called to the insanitary conditions of the Cheam mortuary. He had received no report from the coroner, but had communicated with the urban district council. Replying to Dr. O'Donovan, he said he had not received complaints that a considerable number of mortuaries throughout the country were in an insanitary condition. He would be glad to hear of any specific cases.

Milk Publicity Fund and Supplies to Schools.—On March 26th Mr. Harcourt Johnstone asked the Minister of Agriculture what arrangements were contemplated, or had been made, to assist the supply of milk in schools by means of his proposed grant of £500,000, and if any provision was to be made to guarantee the purity of the supplies. Mr. ELLIOT said it was for the Milk Marketing Boards, in the first instance, to frame programmes for expenditure from the Milk Publicity Fund, which must include arrangements for the supply of milk to schools at reduced rates. There was no reason to delay the conclusion of contracts in the ordinary way for the supply of milk to schools for the summer contract period.

Death from Small-pox.—On March 26th Sir HILTON YOUNG, replying to Mr. Groves, said that during 1933 small-pox was registered as the sole cause of death of one male, aged 52,

Diplomas in Ophthalmic Medicine and Surgery were granted, jointly with the Royal College of Surgeons, to the following candidates:

H. W. Appleby, Edith D. Bower, W. G. Davidson, G. D. Gordon, H. D. Guever, J. N. Jassal, A. R. Khan, F. H. W. Lyle, P. H. Maal, W. H. E. McCrea, G. G. Patel, A. W. Patton, L. G. Scoular, J. Sterne, K. H. Singh, Edie Slater, P. I. Thomas, R. L. H. Townsend.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

Pharmacy—A. J. L. Baker, J. L. Freer, J. C. Harvey, F. W. O'Donoghue, F. D. Peterson, J. D. Taylor, F. H. N. Whitehead.
Medicine—A. J. L. Baker, A. C. E. Cole, R. Frankling, J. Lapschitz, E. C. M. Palmer, F. H. N. Whitehead.
Pharmaceutical Science—A. J. L. Baker, M. I. Cerran, R. C. M. Palmer, H. Petrovskis, J. H. Taylor, F. W. Thomas, F. H. N. Whitehead.

Pharmacology—A. J. L. Baker, R. N. Cressley, M. F. Curran, B. David, J. H. Flavin, F. H. N. Whitehead.

The diploma of the Society has been granted to A. J. L. Baker, A. C. E. Cole, B. David, R. Frankling, J. L. Freer, J. C. Harvey, J. Lapschitz, E. C. M. Palmer, J. H. Taylor, and F. H. N. Whitehead.

Medical News

The one hundred and fourteenth annual general meeting of the Hunterian Society will be held at Simpson's Restaurant, Chancery, E.C., on Monday, April 9th, at 7.15 p.m. After the annual meeting Sir Frederick Holdway will give an address on "The Debt Veterinary Science owes to John Hunter."

A meeting of the Eugenes Society will be held at the Linnean Society's Rooms, Burlington House, Piccadilly, W., on Tuesday, April 17th, at 5.15 p.m., when there will be a symposium on birth control. The speakers will be representatives of the National Birth Control Association and the Society for the Provision of Birth Control Clinics, with Sir Humphry Rolleston in the chair.

A course of lectures on pathological research in its relation to medicine has been arranged for the summer session at the Institute of Pathology and Research, St. Mary's Hospital, London, W. These lectures will be given in the lecture room of the Bacteriological Department of the Institute on Thursday afternoons at 5 p.m., from August 12th to May 31st, inclusive. The lecturers are: whist Alnroth Wright, Professor A. Bethe (University of Marburg), Mr. Hugh Cairns, Sir Bernard Spilsbury, Professor J. B. S. Haldane, Professor J. C. Drummond, viator E. N. Da C. Andrade, and Dr. Leonard "Schrock. The course is open to all members of the medical profession and to students in the medical schools without fee.

A post-graduate course on the medical and hydrogeological treatment of diseases of the digestive system, as well as nutrition in the light of recent research will be held under the direction of Professor Maurice Villaret at the Hôpital Necker, Paris, commencing on April 23rd and lasting for a fortnight, and will be followed by a visit to Vichy, where the last two lectures will be given. The fee is 200 francs. Further information can be obtained at the Laboratoire de l'Hydrologie et Climatologie, Faculté de Médecine, Paris.

The Fellowship of Medicine announces that Dr. Clark-Kennedy's thirteenth lecture-demonstration, at 11, Chandos Street, W., on April 17th, will deal with cardiac murmurs. On April 14th, at 3 p.m., Mr. Mortimer Woolf will demonstrate surgical cases at the National Temperance Hospital. On April 11th Mr. Lindsay Rea will give a demonstration on the fundus oculi for M.R.C.P. candidates. On April 11th, at 11, Chandos Street, at 8.30 p.m., Dr. Ellman will begin a series of lectures on the diagnosis and treatment of chronic diseases of the chest in general practice. An afternoon course in infants' diseases will be given at the Infants Hospital from April 9th to 21st. On April 14th and 15th the Southend General Hospital is holding a course in general medicine

and surgery. The British Red Cross Clinic has arranged a course in rheumatism on Tuesdays and Thursdays, from April 10th to 26th, at 8.30 p.m. Other forthcoming courses and demonstrations include ophthalmology, at the Royal Eye Hospital, April 16th to 28th; x-ray films and electrocardiograms (for M.R.C.P. candidates), at 11, Chandos Street, April 16th, 17th, and 19th, at 8.30 p.m.; and three lectures (free to members and associates of the Fellowship), at 4 p.m., on April 19th, 26th, and May 3rd. Brief particulars are given in the diary column of our Supplement each week.

At the next conference of the German Society of Internal Medicine, which will be held at Wiesbaden from April 9th to 12th, the main topics for consideration will relate to problems of inheritance and transmission in respect of the circulatory system, kidneys, and nerves, pulmonary diseases, and psychological conditions; the principles and problems of neurological localization; and the physiology, chemistry, and therapeutics of the sexual hormone. Vitamins will be discussed in a joint session with the German Society for the Study of Diseases of the Digestion and Metabolism.

The next meeting of the International League Against the Venereal Peril will be held at Madrid in May.

The Middlesex Hospital has received from Mr. E. W. Meyerstein of Dinton Green a gift of £30,000, to develop a new department of radiotherapy. The hospital has also received a new gift of £10,000 from Lord Woolavington, making Lord Woolavington's total benefactions to the hospital £135,000, and a new gift of £10,000 from Mr. W. H. Collins, donor of the Collins X-Ray Diagnostic Unit, which brings Mr. Collins's benefactions to £35,000.

Dr. H. B. Fletcher of Dronfield, Derbyshire, is retiring from the urban district council, of which he has been a member for fifty years. For twenty-one years he has been chairman, and for twenty-five years a J.P. In 1894, when the Dronfield local board became an urban district council, there were twenty-one candidates for nine seats, and he headed the poll. Dr. Fletcher is retaining his membership of the Derbyshire County Council, to which he was recently re-elected; he has been a member of it since 1919. In view of the widespread appreciation of his untiring work and many services to the local community, a testimonial fund has been opened. Dr. Fletcher, who is a member of the British Medical Association, received his medical education at Edinburgh.

In the *Journal* of March 24th (p. 565) reference was made to presentations to Dr. Luke Gerald Dillon upon his retirement after practising for fifty years in Seaham. A further presentation, in the form of a massive silver loving-cup from the medical practitioners of the county of Durham in recognition of his services as a practitioner and chairman of the local medical and panel committee, was made to Dr. Dillon by Dr. David F. Todd (honorary secretary of the committee) at a complimentary dinner at Durham on March 17th.

Dr. Walther has been elected president, Dr. Siredey vice-president, Professor Achard general secretary, and Dr. Brouardel annual secretary, of the Académie de Médecine for 1934.

Professor Burian of Prague and Dr. Clauoné of Paris have organized an international course in plastic surgery. The course will be held in Paris from May 14th to 18th and in Prague from May 19th to the 26th. The fee is 300 francs. Further information can be obtained from Dr. Clauoné, Rue Scheffer, 29, Paris.

The total number of doctors in Japan in 1932 was 50,068, an increase of 1,969 over that in 1931.

The following appointments have recently been made in foreign medical faculties: Dr. Richard Sirbeck of Heidelberg, professor of internal medicine at Berlin; Dr. Aubertin, professor of experimental medicine at Bordeaux; Dr. Serr, professor of medical pathology at Toulouse; Dr. Ladislav Melanowski, professor of ophthalmology at Warsaw; and Dr. E. Cylarz, professor of internal medicine at Vienna in succession to Professor J. Pal.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBER** of the British Medical Association and the *British Medical Journal* is **EUSTON 2111** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:
EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology
Western, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER

(Advertisements, etc.), *Articulate Western, London.*

MEDICAL SECRETARY, Medicera Western, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshough Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Paraesthesia In a Case of Aneurysm

"H. S. O." (London, S.E.) writes: I have a patient with abdominal aneurysm whose chief complaint is a sensation of burning all over the body, and worse in the lower limbs. I have tried numerous remedies, except opiates, and would be glad of suggestions. Aspirin gives some relief.

"Beo Wine"

"FERMENT" asks if any reader can tell him the nature of the ferment which is used in the manufacture of so-called "beo wine," how and where it is procured, and its action.

Signing Prescriptions for Dangerous Drugs

"M.D., M.R.C.P." (Hove), writes: On two occasions lately chemists have called my attention to the fact that signatures for drugs prescribed under the Dangerous Drugs Acts are not valid if made as a carbon copy, as is customary when using a duplicate prescription book, but that such signatures should be written separately on the prescription itself. I should be glad to know if this is the case. I have signed very many prescriptions in the ordinary way, using a duplicate prescription book in which the prescription and signature are actually a carbon copy, and they have not been queried before.

•• We understand from the above inquiry that our correspondent retains his original signed prescription, giving a carbon copy to his patient. Why not reverse the procedure and give the original prescription to the patient or, as an alternative, sign the copy instead of the original? This would save all anxiety to our friends the pharmacists, and avoid raising an awkward issue.

The Pox Doctor's Clerk

"R.A.M.C. (ret.)" writes from Reading: With reference to Dr. Philip Gosse's query in the *Journal* of March 24th about the phrase "Lucky as the pox doctor's clerk," and in amplification of the reply in the *Journal* of March 31st, which does not touch upon the "lucky" portion of the query, I inquired from a friend who served in the ranks of the K.O.S.B.'s, and he said that whenever there was any great piece of luck coming to a man in the battalion it was common to hear the remark, "He's as lucky as a pox doctor," the inference being that the V.D. specialist was always fully employed, and, in consequence, well paid, and therefore lucky. The greater including the less, it may be taken that his clerk (if any) was also in a fortunate position.

Income Tax

Payment or Part Payment of Locumtenent

"P. P." was unfit for work for three months, and unable to carry out the duties of an appointment he held or other miscellaneous professional work. During the period he received his salary, and the authority paid a locumtenent.

"P. P." also made payments to the same deputy for other work. How should "P. P." deal with his income tax return?

•• He should include all amounts received, and can deduct the cost to him of the locum services. That cost would include the cash payments and a reasonable sum for board and lodgings. Naturally the latter sum will vary according to the total cost to "P. P.," but a reasonable amount can usually be agreed with the taxing authority without much trouble.

Special Receipts—Liability

"W. G." inquires in the case of (a) an amount "received by way of adjustment when a company has reduced a stock to another stock," and (b) when a life assurance premium has after a long period ceased to be payable, and a certain sum is credited to the policy as a reversionary bonus, whether such receipts or credits are liable to income tax.

•• They appear to be capital receipts or credits, and not liable to income tax.

Board, etc., of Locumtenent

"A. B." wishes to know the usual amount allowed for board, lodging, and laundry of a locumtenent. He has claimed to deduct £2 2s. per week, but the inspector of taxes refuses to allow more than 25s. per week.

•• The amount should represent a reasonable estimate of the practitioner's out-of-pocket expenditure. Consequently the answer to "A. B.'s" inquiry must depend on (a) the total domestic expenses, and (b) the ratio applicable to the locumtenent, and obviously no definite rule can be laid down to cover circumstances which vary so much. Normally, however, "A. B.'s" estimate of £2 2s. would be nearer the mark than the inspector's figure of 25s.

LETTERS, NOTES, ETC.

Honour Where Honour is Due

Dr. W. LEES TEMPLETON (London, N.) writes: The ingenious assumption of credit for amelioration of symptoms by the laity after the use of various external applications is illustrated by the two following cases seen on the same day. *Case 1.*—Male, aged 27, with lobar pneumonia, had his crisis on the third day of illness. To ensure that the patient should not be encouraged to take undue liberties the situation was explained to the relatives, when one of them (his mother) remarked with reference to the very early fall of temperature: "Of course, that must have been due to my grandmother's cure for temperature, which I applied—namely, wetting the back of the patient's back with vinegar!" *Case 2.*—Male, aged 30, with renal colic and blood in the urine. The cessation of the pain coincided with the arrival of the patient's mother, who promptly applied a mustard plaster to the affected area and claimed full credit for the cure. Needless to say, the patient has since gone into hospital for full investigation.

Aspirin Poisoning: Attempted Suicide

Dr. S. LIRETZ (Edinburgh) writes: It would perhaps be of interest to record a case of attempted suicide by aspirin poisoning in which 600 grains of aspirin were taken at one time without the desired fatal result. Martindale quotes a case of 485 grains, with recovery. In my case, a man aged 48 years, after a drinking bout, took 120 five-grain tablets at about midnight. One and a half to two hours later he became violently sick, and continued to vomit until about 11 a.m. There was no diarrhoea. When I first saw him, about 7 p.m. on the same day, he was comparatively well, with a normal pulse, and required no active treatment. His only subjective symptom at that time was a feeling of discomfort in his head and neck, which he described as "like water rushing through a large pipe." His only other symptom was a very acute but transitory attack of perspiration, which preceded the vomiting.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 44, 45, 46, 47, and 50 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 48 and 49. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 144.

RADIUM TELETHERAPY

LATEST MODIFICATION OF THE WESTMINSTER APPARATUS* AND ITS USE*

BY

H. T. FLINT, D.Sc., Ph.D., M.R.C.S., L.R.C.P.

L. G. GRINNETT, B.Sc.

E. ROCK CARLING, F.R.C.S.

AND

STANFORD CADE, F.R.C.S.

(With Special Plate)

Westminster Hospital has made use of distance mass radiation with radium since 1929. In all, five different machines have been constructed and employed for treatment of patients and for research. Masses of 1 gram, 4 grams, and 2 grams have been used. Increased experience has dictated necessary modifications of the container, the distribution of radium within it, and the methods of treatment. The successive designs embody the results of our experience. A brief résumé of the earlier types will be of assistance in making clear the reasons for adopting the current form, whose successor will, no doubt, eventually incorporate further improvements.

When the work began the method of applying large quantities of radium placed outside the body was still at an early stage, and we were unable to discover that any definite principles had been laid down for guidance in the technique of treatment. For example, it was impossible to obtain any satisfactory answer to the question whether the beam of radiation should be broad or narrow. This question, put in another way, asks whether we should irradiate only the malignant tissue and its immediate surroundings or a wide area of healthy tissue. Our experience has taught us that it is better to concentrate on the malignant area and a small area of healthy tissue only. We adopt as an important principle the production of a narrow beam of radiation in contrast with the field of our early apparatus and of some of those in use on the Continent. In some cases these fields are more accurately described as clouds of gamma rays rather than beams.

The first "bomb" was rapidly constructed to utilize an unlooked-for loan of a gram of radium. The principles and measurements were those of Regaud's cupola, which was selected after seeing those of Sluys, Mallet, Cheral, and Perussia, and analysing their fields as well as those of Regaud and Failla. Berven's apparatus at that time was small: little more, in fact, than a method of surface application of a few hundreds of milligrams. Our second apparatus was a modification permitting three positions of the four one-gram aggregates at the "corners" of a field no longer strictly square.

In the third apparatus the radium (which was supplied in twenty tubes) was arranged in a circle, the circumference of which could be altered at will by drawing the tubes radially towards the centre. In all these three types the protective casing was very thick, and the weight of lead precluded movement of the whole bomb on more than one axis. Elaborate apparatus was therefore necessary to bring the patient to the bomb in any desired position. Notwithstanding the mechanical perfection of this device two difficulties arose: (1) the time taken in application was greater than should be permitted if the personnel engaged was to be entirely safe; and (2) allowances for the comfort and unavoidable movements of a patient treated for one or more hours made strict accuracy of orientation and distance impossible.

Before this instrument had been in use three months it was decided that a different principle must be adopted: (1) the field must be small; (2) the apparatus containing the radium must be brought to the patient and not the

patient to the apparatus; (3) the skin-radium distance must be variable at will within certain limits; (4) the diminution of lead screenage necessary to permit of free movement of container must be compensated by increased distance between personnel and patient. A much smaller cupola was therefore constructed, pear-shaped, supported and counterbalanced on long lever arms mounted on a wheeled stand. The container could be moved on any axis, and the radium approximated or withdrawn by mechanical controls at a distance of five feet from the radium. This bomb housed the fifth gram of radium at our disposal, and, though faulty in some respects, led the way directly to the design of the current model.

Adverse comments have been levelled at the design of our four-gram container by those who had no personal experience of the working of such an apparatus. For the most part these strictures were the echoes of our own criticisms, which were explained in detail to those who inquired, and were anticipated by our fourth apparatus, which was the experimental form for a new four-gram model had the radium remained with us. It was used for two years as a one-gram machine, and is now superseded by the current model, which contains two grams of radium.

THE PRESENT MODEL

When a radioactive source of small dimensions is placed at the end of a channel in a block of lead the rays penetrate the metal bordering the opening, and a spreading effect is caused outside the region which is the prolongation of the channel; lateral regions of appreciable intensity are produced, and tend to destroy the beam-like character of the gamma rays. It has not, in fact, the character of a beam of light, such as would be produced if the radioactive source were a light source. The effect of spreading can be reduced if the channel has thick walls, but when lead alone is used the apparatus becomes inconveniently large. We have overcome this effect to an appreciable extent by making the lower end of the channel of gold, which, being more absorbent of gamma rays than lead, causes the field to fall off more rapidly at the boundary. By this means we succeeded in producing a remarkably good beam. Platinum would produce an even better result, but at greater cost. The external diameter of the bomb is approximately 14 cm., the internal diameter of the radiation channel 3.5 cm., while the gold mouth is 1 cm. thick and 3 cm. long. Complete details and dimensions will shortly appear in *Acta Radiologica*.

A second point of importance concerns protection. With regard to the patient there is no difficulty. No harm has resulted up to the present from irradiation of normal tissues of the patient by the weak parts of the field bordering the intense regions in our bombs. The concern of those in charge of massive radioactive sources is chiefly for those whose duty it is to apply the treatment. Our calculations of fields permissible in the neighbourhood of the apparatus were originally based on our experience of the effects observed on the skin, and especially from the Radiumhemmet, Stockholm. However, upon such data as we could collect from other sources, rules have now been laid down and published in a pamphlet issued by the Health Organization of the League

* Continuation of articles in the *British Medical Journal*, May 11th and August 3rd, 1929; February 8th and July 19th, 1930.

of Nations (Geneva, 1931) for guidance of radium workers and with a view to safeguarding them. Our subsequent measurements with a calibrated celluloid-walled electro-scope have shown that we are within the safe limits. It was very interesting and satisfactory to us to note that calculations made by the simple application of the inverse square law and the absorption of the apparatus gave results agreeing with the electroscope. But whatever may be done to guarantee the safety of the workers the fact remains that the bomb is a weapon calling for careful handling. The chief factors in protection are ultimately distance and common sense.

APPARATUS AND METHOD OF APPLICATION

We have reduced the bomb to quite small dimensions and its weight to 38 lb. It is counterpoised over pulleys, and is able to rotate about an axis through its centre of gravity. It is thus easy to handle, and will stay in the position in which it is placed. The patient comes into the treatment room with a metal holder in the shape of a truncated cone of correct angle, fastened by elastic webbing already attached in such a position that when the bomb fits into it the radiation is directed to the lesion. Figs. 4 and 5 are intended to make clear the method of application. The patient sits on a couch, and is then swung into position under the bomb, and he can either push the apparatus into contact himself or it can be fixed by an attendant, who stands a few feet away and makes the necessary adjustments by means of a rod held in the hand. The actual fixing is at present made by means of an elastic band, which fastens the metal cone to the bomb and maintains the same relative position of bomb and patient, although the latter may make such slight movements as are to be expected from anyone stretched on a couch or sitting in a chair. The method of fastening is clearly capable of considerable variation, but it must be easy to work, and there should never be any need for the attendant to place his hand on the bomb, even though the amount of radiation through the upper half of it is very small.

CLINICAL APPLICATION OF MASS RADIATION

The object of mass radiation (or the use of a bomb) is to deliver to the tumour in all its parts gamma radiation of the highest practical intensity with the least possible damage to the skin and surrounding normal tissues, except the actual tumour bed. The advantages derived by the patient from such radiation are as follows:

1. No operative intervention is necessary, as in interstitial radiation.
2. Much more accurate treatment is possible than with plaques, collars, or other surface methods.
3. The depth intensity is greater.
4. The situation of the tumour is of less importance, as access to it is not so vital a factor, providing the quantity of radium available is sufficiently great.
5. The destructive effects on lymphocytes are less than with wide plaques of lesser intensity.

The efficacy of the method depends mainly upon the ratio between the quantity of radium and radium-tumour distance. From the experience gained in the use of the various bombs it can be postulated that for efficient mass or distance radiation it is necessary to make use of multiple ports of entry of small diameter, as it is thus possible to reduce the skin reaction to a minimum and increase the tumour dose to any desired quantity.

The selection of cases suitable for distance or mass radiation is dictated by practical considerations of the surface area to be treated, the radio-sensitivity of the growth, and the quantity of radium available. With the present apparatus and two grams of radium at a distance of 3 cm. erythema of the skin is obtained in six hours, and peeling in seven hours. Intermittent irradiation of

one hour per port of entry per day is found convenient and safe. Occasional periods of rest enable the total dose to be increased considerably. For the past year the cases treated consisted chiefly of pharyngeal cancer, malignant glands (neck, axillae, groin), metastases in the skeleton, mediastinal sarcoma, sarcoma of long bones, and selected cases of cancer of the breast. In a number of cases radium treatment and high voltage x-radiation were combined with great benefit to the patient.

The reactions in the skin and mucosa are similar to those obtained by other methods of radiation. With experience it is possible to control these reactions from a slight erythema to desquamation and selective radio-dermatitis. The degree of reaction permitted to occur varies with several clinical factors. An initial reaction occurs early in the treatment, and manifests itself by oedema and a primary erythema. The reaction proper occurs between the sixteenth and eighteenth days, with the methods at present used. The effects on the general health and on the blood picture are appreciably smaller than with the earlier machines. Radium-sickness at the Westminster Hospital Annex has disappeared with improved technique. The blood counts show a progressive fall in the total number of white corpuscles, with a greater relative fall of lymphocytes. These changes, however, are far less marked with the present bomb than with extensive plaques—although the latter contain ten to twenty times less radium than the former—principally because less normal tissue is irradiated, and the total surface area treated is never extensive.

RESULTS OBTAINED FROM BOMB RADIATION

As we are not concerned in this paper with either statistical results or any other consideration except the possible value of mass radiation, it may be convenient to enumerate the results obtained, and contrast them with those of other methods of radium therapy.

1. Proved squamous-celled carcinoma of the buccal mucosa, floor of the mouth, palate, tonsil, lateral pharyngeal wall, pyriform fossa, and extensive carcinoma of the larynx have been made to disappear *in toto* with complete healing. They were undoubtedly selected cases; they represent so far early results; they are by no means a large proportion of the total cases treated; but they illustrate that squamous-celled carcinomata in these sites, irrespective of their clinical degree of operability, are amenable to a form of treatment not unpleasant to the patient, accurate, scientific, and safe both to the patient and to the personnel.

2. Cervical and inguinal glands secondary to squamous-celled carcinoma, fixed and inoperable, responded to treatment in certain cases. They are selected as illustrating a type of case which has proved a failure with collars, plaques, and needles, and which is by common consent "inoperable," even in the judgement of the most fearless and skilled operators.

3. Spheroidal-celled carcinoma of the breast, in selected cases, submitted to the bomb as unsuitable for surgery or needling, have led to disappearance of the primary growth and axillary glands. Inoperable tumours have retrogressed so satisfactorily as to permit surgical removal. This should not be taken as an indication that we consider the bomb to-day to be the treatment of choice for all, or even many, cases of cancer of the breast, and does not imply that surgery, or needling, or the two-stage irradiation by radium, are superseded; nor does it reflect on the results obtained recently by x-radiation alone in cancer of the breast. It is meant to convey only that the bomb has a useful place in the treatment of cancer of the breast. When and how to apply it requires judgement, knowledge of the disease, and appreciation of the likely failure or success of other methods.

4. Bone sarcomata, in the long bones and in the vertebrae, have been made to ossify, and have been seen to become replaced by apparently normal bone tissue for periods up to two and a half years, with relief of symptoms. Arrest of the disease locally, however, must not bring forth false hopes as to subsequent appearance of visceral metastasis.

It is therefore a legitimate conclusion that mass radiation at a distance by means of the so-called bomb is not only a useful weapon in the treatment of cancer, but a weapon so far unique in its possibilities and safe in its application. Besides the purely clinical use, the five bombs used at Westminster Hospital in the past four years have led to a much better appreciation of radium therapy. The bombs have been employed for the purpose of physical and biological research, and the following point to which we have paid attention is worthy of consideration.

From the observation of Spear and Grimmer (British *Institute of Radiology*, vol. vi, No. 67, p. 38) it would appear that, so far as inhibiting cell division is concerned, the most efficient way of using radium is to make use of a particular intensity, for, as a result of a series of experiments on tissue cultures *in vitro*, it is clear that biological response to gamma rays depends markedly on the intensity at which they are applied: if too great or too small an intensity is used the radiations are less effective. We have attempted to keep near to the useful intensity. The import of this observation is not yet completely clear, but we mention it here as a warning note to those who may be using large masses of radioactive material. For the natural tendency to produce the highest possible intensity with it may not necessarily be fruitful of good results.

This represents the progress we have made up to the present in the design and application of our apparatus. Daily use continually suggests improvements, and we have come to the conclusion that the best form of bomb would be one which contains the radium only during the period of treatment. This is certainly to be recommended in cases where 5 or 10 grams of radium are available. There is the obvious advantage that the patient can be placed carefully and accurately in position, since there is no haste on the part of the attendant to get out of the treatment room. There is also the advantage that the bomb can be much lighter, as almost the whole of the lead in its upper half can be removed; the latter is required to protect the attendants while making the final adjustment, and adds to the weight of the apparatus. It is possible to make up the active source in the form of a sphere, and to introduce it into the apparatus by rolling it down a tube. An alternative is to attach to the radioactive source a small motor-driven or pneumatic carrier, which would run into position when everything is prepared, and then run back again into the safe at the end of the exposure. Between treatments it would be kept in a lead safe, and when the patient was in position it would be projected into the bomb by an operation performed outside the room. In this way the attendants would be absolutely protected, and the efficiency of the treatment increased by the improvement in accuracy in placing the patient in the beam of gamma rays.

Daily personal experience over a long period of the difficulties and dangers attendant upon the accurate application of large masses of radium to the skin surface in all parts of the body, in such a way that the beam always traverses the tumour, has led, we hope, to some skill in the observance of the required "ritual": it has certainly led to increased respect for the dangerous possibilities inherent in its use by untrained or inexperienced people.

270 CASES OF FRACTURED SPINE RADIOLOGICALLY CONSIDERED*

BY

OWEN L. RHYS, M.D., B.Ch.

RADIOLOGIST TO THE CARDIFF ROYAL INFIRMARY AND TO THE
PRINCE OF WALES HOSPITAL

(With Special Plate)

Until x rays made it possible to discover with certainty fractures of the spine the diagnosis of such injuries was usually confined to those cases in which there was an obvious injury to the spinal cord, with or without bony displacement. Since the introduction of efficient x-ray apparatus, and particularly since lateral views of the spine became available, it has become apparent that fractures of the spine are infinitely more common than was generally supposed. Such injuries are rare in ordinary occupations, and even in London dock areas they are comparatively scarce. In such localities they usually result from buffer injuries, or from falling into the holds of steamers, and there is very little to be found in surgical literature dealing with these cases.

But in coalfields such as those of South Wales, fractures of the spine are so common as to constitute the most frequent form of grave accident. When the occupation of the miner is considered, this is only a natural result. He works with the constant possibility of a fall of roof, sometimes amounting to tons, suddenly pinning him to the ground. The resulting injury varies according to the position that the man is in at the moment, whether standing, kneeling, or lying. If the fall comes on his head or neck, he is likely to sustain a fractured skull or a fractured cervical spine, and the result is, of course, often fatal at once. One reads of these cases almost daily, and in South Wales and Monmouthshire alone about 220 miners are killed outright each year. These unfortunate men never reach a hospital at all, but, from inquiry, I find that many of them have fracture-dislocation of the spine. If the man is in a stooping or kneeling position he may sustain a fracture of any part of the spine, a fractured pelvis, a fracture or dislocation of the hip, or a dislocation of spinal or sacro-iliac joints. Sometimes the original fall knocks the man flat, and, further falls occurring, he may sustain fractures of any of these parts.

MATERIAL CONSIDERED

Many of these men sustain serious spinal cord injury without fatal results, and some of them remain bed-ridden for many years. I have not included any of these in the series I am dealing with. The 270 cases of fracture referred to in this paper have all walked into my consulting room in the last five years. They have been sent to me in connexion with claims under the Compensation Act, and the vast majority of them have been miners referred by the South Wales and Monmouthshire Coal Owners' Indemnity Society. A few of them have been in dock accidents and other types of injury. I have not included fractures or dislocations of the cervical spine, of which I have had several, but have confined this investigation to the dorso-lumbar region, and dealt only with the period of five years. The investigations were carried out entirely from the Compensation Act point of view and not from that of surgical treatment. The length of history of these cases when seen by me varied from a few days to very many years. As many as 201 of them had a history of under five years.

TYPES OF FRACTURE

The majority of the fractures have been of the indirect variety—that is, to say, the stone has fallen on the

* From a paper read before the Medical Society of Wales, 1931.

shoulders and doubled the man up forwards, and the resulting injuries have been fractures of the bodies, of the transverse processes, and, rarely, of the laminae. The commonest type of fracture of the bodies has been the wedge fracture, sometimes referred to as Kummell's disease. In this condition the affected vertebra has received a squeeze on its upper and lower surfaces, the effect of which has often not appeared in a radiograph for many months after the injury. On admission to hospital the patient is found frequently to have a spine radiographically normal, but in a few months one vertebra, and sometimes two, show wedging. I have, however, seen a definite wedge fracture quite apparent within a week of the injury. The intervertebral surfaces remain smooth and the intervertebral spaces remain unaffected.

I think it is unfortunate that the name Kummell's "disease" has been given to this condition. When Kummell described this appearance in 1895—that is, before any x-ray examination was possible—he imagined that an injury had caused a rarefying osteitis of the body of the vertebra and that after a time the body collapsed, as it does in Pott's disease. I prefer to call this condition Kummell's fracture or "wedge fracture." The injury is originally a fissure, sometimes a stellate fissure, radiating from the centre of the body towards the rim, and it is easy to understand how the pressure of the very hard elastic intervertebral disks on this comparatively soft vertebral body would cause a gradually increasing collapse, with, finally, almost complete obliteration of the anterior portion. I have had shown me by Dr. Abeles of Frankfurt some excellent slides illustrating these changes. I think that to curtail the amount of wedging it is essential to prevent the pressure exerted by the disks by the use of steel and leather supports, which will prevent sagging of the spine.

The next common type of fracture is that in which there has been an immediate break in the body or bodies, usually with some displacement, and these cases—especially where there is comminution—are, of course, much more serious and rapid in their effects. Leaving out the effect on the spinal cord, one finds that the effect on the bones is usually that the normal vertebra above the broken one erodes the injured body and causes considerable distortion. Of the 270 cases under review 263 sustained fractures of bodies and 176 of fractured transverse processes. In some of the cases several bodies and several processes were broken in the same spine. Tabulating the frequency of these injuries, the following figures were obtained:

Bodies Involved			
8th dorsal	... 3	1st lumbar	... 58
9th dorsal	... 3	2nd lumbar	... 55
10th dorsal	... 2	3rd lumbar	... 37
11th dorsal	... 19	4th lumbar	... 29
12th dorsal	... 34	5th lumbar	... 23
Total	... 263		

Transverse Processes Involved			
1st lumbar	... 25	4th lumbar	... 46
2nd lumbar	... 33	5th lumbar	... 26
3rd lumbar	... 46		
Total	... 176		

CRITERIA OF DIAGNOSIS

I have confined the diagnosis of fracture to cases where there is: first, a definite wedge, not merely a very slight narrowing of the anterior border of the vertebra, which is frequently seen in working men; and, secondly, where the nature of the injury is such as might reasonably have caused a compression of the spinal column. Claims are frequently made of Kummell's disease in cases in

which the injury could not have possibly caused such a condition. As an example of this:

A man had a slight crush of his pelvis, which cracked his pubis without displacement. Some years later, when he was asked to resume full work, no trace of injury could be found in the pelvis, but a very slight wedging of the second lumbar vertebra having been found, it was claimed to be due to the crack, although the man had never had a symptom suggesting such an injury. In another case in which there was a general kyphosis of the spine, which had obviously taken many years to develop, a recent crush was alleged to have been the cause of the disability.

Again, before admitting any apparent separation of transverse processes to be the result of a crush, I would stipulate that the injury was applied directly over the particular processes involved, and that there was some evidence at the time, such as bruising. There are very many spines in which there are apparent fractures of processes, sometimes with separation, sometimes without, in which no history of injury has been given. In 1910 I published, I believe, the first case of this sort, and since then I have published several articles dealing with these pseudo-fractures. In spite of what one reads in textbooks, I do not know of a case in which a transverse process has been torn off by a muscular effort. In a discussion on this paper, Professor Hey Groves and others raised the point that muscular violence might tear off transverse processes, and with that I quite agree, but I maintain that a voluntary muscular effort will not cause this injury.

Cases are still cropping up in which, radiographically, a line thrown by the edge of the psoas muscle across a transverse process is claimed to be a fracture. As Dr. Gilbert Scott has pointed out, this should not be a mistake often made nowadays, but with so many small hospitals installing plants new users of x rays are constantly coming forward, and these little mistakes are naturally being repeated.

A curious feature in this series has been the rarity of injury to the laminae. I can only explain this by supposing that, where the laminae have been crushed, the spinal cord, too, has probably been injured, and the man has been partially or completely paralysed and unable to travel here for examination.

DISABILITY

As regards the capacity for work after back injuries, there are eighty-seven of these men now working—sixty-eight doing light jobs, seven doing the lighter types of labouring, and twelve doing their ordinary work. It is most difficult to assess the fitness for work owing to the varying personal factor. There must, in the old days, have been scores of men working with fractured spines apparently without serious disability.

In all the cases I am dealing with the question of compensation of course arises, back injuries being uncommon among the uninsured classes, and it is curious to notice how very much worse the complaints of pain become when the diagnosis of fracture has been communicated to the claimant. A very good example of this occurred quite recently.

A man who had been told after previous x-ray examination elsewhere that nothing had been broken, was found to have a fracture-dislocation of his lumbar spine, several fractured ribs, and three fractured transverse processes. He had expressed himself as almost well enough to return to work before another x-ray. The film showed, in addition to the above, a very interesting collection of gall-stones, and, in reporting on the man's case, I added a request to his outpatient doctor that he might send the man back for a face-down film to show the gall-stones more clearly. The man was given the form to bring back, and on his way he read the contents. He was in a state of collapse on returning to the x-ray department, and said his spine was torturing him.

To take the opposite type of patient.

Many years ago I saw an old Welsh collier who insisted on resuming work a few months after a fracture of one of his lumbar bodies. He had a fracture of his pelvis also. He died suddenly at his work from aortic disease. Another man, who was an old bare-fist fighter, worked very shortly after fracturing his spine. But the most interesting case of all was that of a particularly well built young collier who sustained a crush fracture of the second lumbar vertebra, with considerable displacement and fractures of several transverse processes. He enlisted in the Guards and served for six years. At the end of that time he returned to South Wales and claimed for an injury to the spine, which had been found at Aldershot and as a result of which he had been discharged. He was paid a lump sum by the colliery company, and then announced that he was going round the world as a servant to his company officer, and that his spine was perfectly right.

A large amount of displacement of adjoining bodies is possible without any cord lesion. This is particularly the case in the lumbar region, where the tube formed by the dura mater is looser. In several of the films which I showed to the Meynihan Club the vertebrae had been almost pulped and were sometimes lying side by side, so that the cord was displaced laterally at a right angle. In the last month I have seen a curious dislocation in the cervical spine, in which marked displacement is very clearly demonstrated. In this man movements of the neck were full and free, and the only symptoms were paralysis of the right deltoid and loss of the biceps tendon reflex.

A great deal naturally depends on the man himself, but I cannot see why, in the case of a wedge fracture, slowly developing, with smooth surfaces and no pressure on the spinal nerves, there should be any serious loss of working capacity. Compared with the distortion of the spine of the hunchback or some of the bony diseases, these wedge injuries are mild, and they are often as slow in appearing as many of the spinal diseases. But the fracture-plus-erosion type of accident is of course quite different. Here one has rough bony surfaces and an acute angular deformity, and it seems to me that until bony fixation has occurred, to form, as it were, a splint, such a man might suffer pain over a very long period. As regards transverse processes, where the displacement is considerable, they often never unite, though they occasionally may do so with considerable callus. I have one case in which several of them have united to form a solid bony column lateral to the spine. In a few months these separated processes are often painless, and the cracked process in which there is no displacement should cause no pain after, say, three months.

It is impossible to illustrate many of this series, but six skigrams are reproduced on the Special Plate. The examples I have selected speak for themselves. Apart from the tragedy of these unfortunate men being injured in this way and often untreated surgically, there is the other more mercenary view to be taken, for it has a serious bearing in the low state of the coal industry. In compensation these 270 cases mean a tax on the local industry of about £20,000 per annum.

FULL-TERM ECTOPIC GESTATION

BY

E. BRUCE LOW, M.B., Ch.B., D.P.H.

MEDICAL SUPERINTENDENT, SOUTHLANDS HOSPITAL, SHORFHAM-ON-SYDE;
ASSISTANT COUNTY MEDICAL OFFICER (HOSPITALS) AND CONSULTING
OBSTETRICIAN, EAST SUSSEX COUNTY COUNCIL

AND

H. J. MCCURRICH, M.S., F.R.C.S.

HONORARY ASSISTANT SURGEON, ROYAL SUSSEX COUNTY HOSPITAL;
CONSULTING GYNÆCOLOGIST, EAST AND WEST SUSSEX COUNTY
COUNCILS AND THE COUNTY BOROUGH OF BRIGHTON

(With Special Plate)

The treatment of a full-term ectopic gestation is probably unique in the experience of any individual practitioner, and for this reason it is relatively common in obstetrical records. Caldwell, in recording a case of extrauterine pregnancy, with mother and baby living and well, stated that 121 such cases had been reported previously. In 1929 there were actually three cases of full-term ectopic gestation reported in the *British Medical Journal*.

Consideration of the reports of cases of extrauterine pregnancy shows that it usually occurs in a multipara, that the left side is rather more commonly affected than the right, and that the sex of the child is not affected by the side involved. Pre-existing cervical endometritis has been held to be a predisposing cause, but this has not been really established.

In the following case certain unusual features were present. In the first place the case was observed at four critical periods: (1) in mid-pregnancy, probably at the time of secondary intraperitoneal rupture of a mesometric gestation; (2) in the late days of pregnancy; (3) at the spurious labour and subsequent period of devolution; and (4) at delivery by operation. Secondly, certain complications arose. The spurious labour was followed by an intermittent pyrexia, the operation was complicated by an irreducible ventral hernia, and finally there was the occlusion of a ureter.

CASE REPORT

The patient, aged 36, was admitted to the Southlands Hospital on April 6th, 1933. She had had six previous pregnancies—all living children, the youngest being 5 years old. She was sent in from an outlying district as a case of acute abdomen. There was a history of an acute onset of abdominal pain, rigidity, and vomiting twenty-four hours previously; these signs and symptoms rapidly subsided without operation. In the general examination at this time it was noted that she was about five months pregnant, and that the presentation was a breech. She was discharged ten days later free from symptoms. In the light of our subsequent knowledge it seems probable that this attack was one of peritonismus associated with the secondary (intraperitoneal) rupture of an already established and growing mesometric pregnancy.

On July 19th the patient was readmitted, being sent in by an ante-natal clinic as a case of hydramnios. On admission her temperature, pulse, and respiration were normal. The abdomen was pendulous, and there was a small irreducible ventral hernia containing, apparently, omentum only. The foetal tumour was large and tense. What was then thought to be the fundus was one and a half inches below the xiphoid. Neither foetal movements nor heart beats were noted, and the presenting part was indefinite. There was no vaginal bleeding or discharge. There was oedema of both legs associated with varicose veins, with ulceration on the outer aspect of the right leg. The Wassermann reaction was + +. No abnormalities were discovered in the urine. Her condition remained unchanged until August 11th, when she complained of indefinite pains in the back, which had started the previous evening; later she had abdominal pains. Her breasts were secreting.

On examination the foetal heart could not be heard and movements could not be felt, although the patient was convinced that she had felt movement; she "could feel it breathing" was how she expressed it. By vaginal examination there was a slight "show." The external os was softened and patent, and the cervical canal filled with necrotic tissue, which bled easily. On bimanual examination a definite tumour was palpable in the posterior and right lateral fornices, and extending up to the right side of the pelvis, with a smaller mass to the left and higher up. A piece

of the necrotic material was sent to the laboratory, and the following sketches of "possibilities" made (Fig. A).

The necrotic tissue was reported on (by Dr. Shera, County Pathological Laboratory, Hellingly) to show: "Finger-like processes of tissue, which is composed of large polygonal cells, having oval nuclei, some of which show mitosis. The cells are not epitheliomatous, but are probably foetal in origin, and resemble Langhans's cells. They may be derived from a chorion epithelioma, or from placental remains."

By August 13th all pains had ceased. The patient was comfortable, and no further vaginal bleeding occurred. On August 22nd the temperature rose to 100° F., and continued to swing between 99° and 102° for the next ten days; there was also malaise. There were no indications of acute chest

were reduced by blunt dissection, and by separating adhesions between ligatures. The neck of the sac was brought out anteriorly to the line of the peritoneal suture, so that it no longer communicated with the peritoneal cavity. A drainage tube was put into the pouch of Douglas. (Fig. C.)

The patient went on well for a week, and the wound rapidly healed. On the seventh day the temperature rose to 101.8°, and an irregular pyrexia continued for three weeks, for which no definite cause was found. There were some crepitations in the chest, which was later explored by a needle, without finding any fluid. The urine was clear and sterile.

Subsequently a cystoscopy was carried out, and a catheter failed to pass up the right ureter. The patient was then

FIG. A.

or abdominal involvement, and no loss per vaginam. A catheter specimen of urine was sterile and without abnormalities. These negative findings lead now to the inference that the morbid features present were due to systemic intoxication by the products of foetal devolution.

On September 2nd there was a recurrence of haemorrhage and discharge per vaginam. It was found on examination that the external os had completely closed again, and that the same ill-defined masses previously felt were still to be made out on bimanual examination. Here again sketches of "probabilities" (Fig. B) were made for discussion of the case with the consulting surgeon (H. J. McC.) who was called in, acting as deputy for Mr. John Griffith, consulting surgeon to the hospital.

On the same day (September 2nd) a laparotomy was carried out (H. J. McC.) under general anaesthesia. Multiple peritoneal adhesions and bands were encountered, some of them connected with the hernia, and others going to a sac rising out of the pelvis. Exploration with the finger revealed a normal-sized (a non-pregnant) uterus on the left side of the sac. It was not found possible to extirpate the sac without opening it, and, rupture being imminent, the rest of the abdomen was packed off and the sac ruptured; a full-term dead female foetus was removed. Maceration had begun. The fluid in the sac was of a greenish, grumous nature, and appeared to contain meconium.

After removing the foetus the placenta and sac were gradually removed. The placenta was mainly attached to the right side of the pelvis, and between the layers of the right broad ligament. The appendix formed part of the wall of the

FIG. C.

sac, and was removed with it, the stump being invaginated into the caecum in the usual manner. There was a good deal of bleeding on separating the sac from the depths of the broad ligament. The separation was a laborious proceeding. The ureter was not seen, although it was realized that it lay in the vicinity of the attachment of the sac. It was not thought advisable to prolong an already lengthy operation by identifying the ureter. The contents of the ventral hernia

FIG. B.

transferred to the Royal Sussex County Hospital, and an intravenous urogram showed a good shadow of the dye in the left renal pelvis and ureter, but none on the right side. A subsequent cystoscopy (Mr. J. R. H. Turton, acting in the absence of H. J. McC.) with indigo-carmin, which had not been available at the first examination, confirmed the fact that the right ureter was occluded. The patient left the hospital on October 6th in good health.

COMMENTARY

In considering the case one wonders if it would have been better merely to have marsupialized the sac and drained it, which would have been a comparatively simple operation. But it was decided at the time not to leave so much necrotic and probably infective material behind, added to which that potential source of trouble—the appendix—formed part of the sac wall.

Photographs of the foetus and the adventitious gestation sac are reproduced on the plate. A skiagram of the ossification centres was also taken. These confirm that the foetus was a well-developed and full-term female weighing 6 lb. 12 oz. and measuring 19½ inches. Two congenital defects were present: a moderate degree of hydrocephalus and double pes calcaneus, much more marked on the left side.

UNTOWARD EFFECT OF PHENYLHYDRAZINE HYDROCHLORIDE IN POLYCYTHAEMIA

BY

A. M. KENNEDY, M.D., F.R.C.P.

PROFESSOR OF MEDICINE, UNIVERSITY OF WALES, AND DIRECTOR OF THE MEDICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

Now a well-recognized therapeutic agent in polycythaemia vera, phenylhydrazine hydrochloride, has been employed with considerable success in many cases. It has a well-marked haemolytic effect, and reduces the volume of the blood. It has been suspected of producing serious toxic damage to the liver and kidneys, but conclusive proof is lacking. Clinical experience, however, has shown that administration is not always devoid of risk for certain types of patient—for example, those over 60 years, or with marked arteriosclerosis or advanced disease of the liver, kidneys, or other viscera. In them its use should be avoided, or, if tried, special caution is imperative, and the effect of a dose of $1\frac{1}{2}$ or 3 grains should be watched for several days before more is prescribed. In the case described below four short courses of treatment with phenylhydrazine hydrochloride were given without any untoward effect, but a fifth produced a severe haemolytic crisis.

Chart showing the untoward effect of phenylhydrazine hydrochloride and the recuperative response to liver therapy.

HISTORY OF CASE

A collier, aged 38, first came under observation in July, 1932, with chronic polycythaemia, cyanosis, and some enlargement of the spleen. The blood (Group III) reacted negatively to the Wassermann and Kahn tests; the red cell count was 9,560,000 per c.mm. and the haemoglobin 150 per cent. Venesection on two occasions within the first week reduced the red cells to 7,970,000 per c.mm., and nine days later treatment with phenylhydrazine was commenced. Three courses, at intervals of eleven days, were given within a period of seven weeks. The blood count was practically the same before starting each course.

The first consisted of 33 grains administered over a period of eleven days, and as a result the haemoglobin fell by 10 per cent. only, but the red cells were unaffected. The second, 11 grains over four days, reduced the haemoglobin by 6 per cent. only, but the red cell count went up by about half a million per c.mm., and the patient got a severe throbbing headache, which was relieved only by venesection. The third, 33 grains over a period of eight days, reduced the red cell count from 7,400,000 per c.mm. to 5,860,000 per c.mm. and the haemoglobin from 120 to 100 per cent. The success of the third course might be ascribed to some cumulative effect, but the fall in the red cell count did not continue more than three days after withdrawal of the drug. The total amount administered in the first and third courses was the same, but in the latter

the period was shorter. No toxic symptoms appeared. The urine never became dark in colour, vomiting and diarrhoea were absent, and there was no jaundice.

The Haemolytic Crisis

After cessation of treatment the red cell count gradually rose again, the cyanosis became worse, and the spleen slowly increased in size. Four months later the patient lost one to two pints of blood in an accident, and as a result his condition was temporarily improved. He returned for further treatment thirteen months after the last course of phenylhydrazine. At that time (October 30th, 1933) he had 7,720,000 red cells per c.mm. and 126 per cent. haemoglobin. Thirteen grains of phenylhydrazine hydrochloride were taken over a period of seven days, and the red cells subsequently decreased by 560,000 per c.mm. and the haemoglobin by 16 per cent., but the white cells increased by 5,000 per c.mm.

The drug was left out because the patient felt sick and ill, but there was no jaundice and no diarrhoea. The urine contained urates, but neither blood nor albumin. A week after omitting the drug there was a faint trace of albumin in the urine for the first time, and the spleen was definitely more enlarged.

Nine days having elapsed, the phenylhydrazine was repeated for a fifth time, and $1\frac{1}{2}$ grains were given twice daily. After six and a half days — $19\frac{1}{2}$ grains having been taken altogether—the drug was stopped because the patient vomited, and he had diarrhoea with ten loose chocolate-coloured motions in the ensuing twenty-four hours. Next day the patient was slightly jaundiced, and the loose, chocolate-coloured motions were

more frequent. The blood count now (November 27th) was: red cells, 4,980,000 per c.mm.; white cells, 37,600 per c.mm.; haemoglobin, 80 per cent.; colour index, 0.8. This represented a drop of 2,180,000 red cells per c.mm. in the seven days during which the drug had been administered. The patient was looking ill, his countenance pale, earthy, and slightly yellowish, and the lips bluish. The loose chocolate-coloured motions (two to four daily) continued for four days after the omission of phenylhydrazine; the patient vomited once on the second and once on the fourth day, and the spleen grew still larger (two to three inches below the costal margin). The faeces were found to contain very large amounts of urobilin, but only a trace of bile pigment and no blood.

On the day before this last course was started there was a faint trace of albumin in the urine, and this persisted for twenty-four days. A few red blood cells were observed on the first day after the drug was withdrawn and on the succeeding seven days; urates appeared on the second day, and persisted for twenty-eight days; and, on the fifth day, the urine became deep amber in colour and contained a large amount of urobilin. This increased in amount as the number of red cells and amount of haemoglobin diminished, the colour of the urine becoming a deep reddish brown, but bile pigment was never detected.

Red cells and haemoglobin continued to fall *pari passu* and the white cells to rise at an alarming rate, attaining their

maximum (80,000 per c.mm.) seven days after stopping the phenylhydrazine, then declining as quickly as they rose. The red cells and haemoglobin reached their minima together fourteen days after the drug was left out. The blood count then (December 9th) was: red cells, 1,670,000 per c.mm.; white cells, 31,400 per c.mm.; haemoglobin, 23 per cent.; colour index, 0.7. Thus in nineteen days the red cell count had dropped by 5,490,000 per c.mm. and the haemoglobin by 87 per cent., and very large amounts of urobilin were being passed in the urine and faeces. This had resulted from the ingestion of 19½ grains of phenylhydrazine hydrochloride over a period of six and a half days.

Treatment

The patient was now very weak, his head felt "swimming," pallor was very marked, but the icteric tinge had almost disappeared. Diarrhoea, with chocolate-coloured motions containing large amounts of urobilin, recurred, and so, with the object of preventing further deterioration in the blood, a blood transfusion (10 oz.) was given. The downward progress of the case was arrested immediately. Within four days the red cells gained 430,000 per c.mm., the haemoglobin 5 per cent., and the white cells diminished by 13,000 per c.mm., but large amounts of urobilin continued to be excreted in the urine and faeces. As no further improvement was noted after another five days liver extract was administered. The preparation "livogen" (liver extract with haemoglobin and vitamin B) was given in half-ounce doses twice daily (= 4 oz. liver daily). Rapid and immediate improvement resulted. In one week the red cells increased by 1,230,000 per c.mm., the haemoglobin by 20 per cent., and the white cells dropped by 9,000 per c.mm.; the excretion of urobilin in the faeces became very much less, and only a small amount could be found in the urine. After another week the liver extract preparation was omitted, for the red cells were found to have gone up by another 1,940,000 per c.mm. and totalled 5,160,000 per c.mm., the haemoglobin had risen to 74 per cent. (a further increase of 24 per cent.), and the white cell count was practically normal. The faeces were now normal, and the urine contained the merest trace only of urobilin.

A week after stopping the liver extract the red cell count was found to be 6,000,000 per c.mm. and the haemoglobin 90 per cent. The spleen had diminished in size, being just palpable below the costal margin, and the patient was very well.

COMPARISON OF THREE CASES

The serious haemolytic crisis on this occasion resembled that reported by Giffen¹ and by Evans.² In Giffen's patient the red cell count fell 4,650,000 per c.mm. in four weeks; in Evans's it fell 4,000,000 per c.mm. in ten days. In my case the fall was 5,490,000 per c.mm. in nineteen days. In Giffen's case 58 grains (approximately) were taken over a period of thirteen days; in Evans's 12 grains over four days. My patient received 19½ grains during six and a half days; but if the last two courses (given at nine days' interval) are considered as one—making a total dosage of 32½ grains—then the fall in red cells was 6,050,000 per c.mm. in twenty-two and a half days. It is difficult to account for the rapid haemolysis in this case on this occasion. The dose was moderate and well case on this occasion. The dose was moderate and well within the limits suggested by Giffen and Conner³ for initial dosage—namely, from 1.5 to 3.5 grams (23 to 54 grains). Besides, the patient had had three courses of 33 grains, 12 grains, and 33 grains respectively within a period of seven weeks over thirteen months previously, and a moderate haemolysis resulted from the third only. Evans's patient also had had a previous course—38 grains during twenty-five days—with a fall of only 600,000 red cells per c.mm., and an interval of twenty-four days elapsed before the second was started. In the latter, with the alarming haemolysis, the drug used had been freshly prepared, whereas in the former it was old, suggesting that the freshly prepared drug is much more potent; but in my case the same drug was employed on both occasions, so that the question of freshness does not

arise. In Evans's case, too, the capsules in which each dose of the drug was administered during the second course were larger than those in the first, and he feared a mistake; but, on reweighing, the dosage was found to be accurate. The discrepancy in size was accounted for by the fact that the original prescription had been "tamped" and the second "scooped." It is a curious coincidence that the same thing happened in my case. The doses given when the serious haemolytic crisis occurred were made up in larger capsules than those employed on the preceding occasion, but inquiry proved that there had been no error in dosage. The drug in the smaller capsules was firmly packed, whereas that in the larger was loose. It may be that the loosely packed drug was more readily absorbed than the firmly packed.

There were no advanced vascular, hepatic, or renal changes to contraindicate the drug, and the age of the patient was only 38 years. A faint trace of albumin, however, had appeared in the urine on the day before the last course was begun, and persisted until sixteen days after it was stopped. Albuminuria had never been observed in any preceding course. As a result of the haemolysis large quantities of urobilin (but no bile pigment) were excreted in the urine, which deepened in colour to a dark reddish brown. Large quantities of urobilin were also passed in the faeces, giving them a chocolate colour—which might be mistaken for melaena at a casual glance—and diarrhoea was present. The excretion of urobilin diminished as the condition of the blood improved. The first indication of anything untoward happening was vomiting, followed by diarrhoea—loose chocolate-coloured motions—associated with a marked fall in the red cell count, an abrupt rise in the number of leucocytes, and the patient's becoming ill-looking and pale, with a slight icteric tinge.

REGULATION OF DOSE

No hard-and-fast rule can be laid down as regards dosage for initial courses for patients, even otherwise healthy: 1½ grains twice, and possibly three times, a day should suit most cases. The total dosage suggested by Giffen and Conner (23 to 54 grains) is probably safe as a general rule, but individual patients vary, and must be watched carefully for the appearance of icterus, the colour of the urine observed daily, the amount of urobilin excreted noted, and, of course, frequent blood counts done. Once the red cells and haemoglobin begin to show a definite continuous fall extreme caution is necessary, and it may be wise to withdraw the drug, temporarily at any rate, for the fall may continue for a week or more afterwards. In any case it is always advisable to omit the drug when the red cell count approaches 6,000,000 per c.mm. A sudden and considerable rise in the leucocyte count is also an indication of possible danger approaching, although Sealy⁴ is inclined to think it unreliable.

Should the fall in the red cells become alarming it would appear that a blood transfusion will arrest its progress. This obtained in my case, but further improvement seemed to lag until the liver extract preparation "livogen" was administered. The rapid and remarkable improvement in the blood which followed would justify the use of liver extract, even without transfusion, in any other case presenting a similar haemolytic crisis from phenylhydrazine hydrochloride. The immediate and great response to liver therapy might be a matter for speculation, for, as the result of administering the equivalent of 1¼ lb. of liver daily, the red cells increased by 3,270,000 per c.mm. in fifteen days, suggesting that the marrow was hypersensitive to the intrinsic factor of Castle. The possibility of polycythaemia vera being due

to an excessive secretion of the intrinsic factor by the stomach, or to hypersusceptibility of the marrow to it, has been mooted by Morris.³ Whether phenylhydrazine might have some inhibitory or destructive effect on the intrinsic factor, or on the cells producing it, has not been suggested.

SOME THEORETICAL ASPECTS OF COLLAPSE THERAPY

BY

F. H. YOUNG, M.D.CANTAB., F.R.C.P., D.P.H.

PHYSICIAN, CHARGING CROSS HOSPITAL, AND THE BROMPTON HOSPITAL FOR DISEASES OF THE CHEST

A recent discussion on the results of collapse therapy in pulmonary tuberculosis was remarkable for the lack of attention which was paid to the exact consequences following on the various forms of collapse therapy, when considered in terms of anatomy and pathology. Collapse therapy brings about, primarily, mechanical and anatomical changes, and it is only when these changes react favourably for the individual that there is therapeutic benefit. At present our knowledge of the immunological processes which determine success or failure in the treatment of pulmonary tuberculosis is very slight, and hence a mechanical change may occasionally end in an unexpected result. The following case is a good example.

A man, aged 40, with diabetes and pulmonary tuberculosis in the upper half of the left lung, was admitted to the Brompton Hospital with a view to artificial pneumothorax treatment. While in Brompton the insulin requirement increased, and fresh disease appeared in the other lung, which spread rapidly, in spite of complete rest and large doses of insulin. After the patient had been going rapidly downhill for about six weeks he was allowed to go home, as I thought to die. Six months later he appeared in the out-patient department looking very well. His history and x-ray examination showed that he had had a spontaneous pneumothorax on the left side, with the result that the pulmonary tuberculosis became quiescent, and was so when I last saw him three years afterwards.

Although unforeseen results may occur, it is obvious that the clearer the idea the user of collapse therapy has of the exact anatomical changes he wishes to induce in the lung and of the effects which will follow these changes, the greater the benefit that is likely to accrue. The considerations put forward here are treated from a theoretical point of view, and cases are quoted merely as examples to illustrate the points made. The former may, however, throw some light on the fact that, while collapse therapy is universally considered to be beneficial, the details of its use are the subject of considerable controversy.

EFFECTS OF COMPLETE PULMONARY COLLAPSE

Given a free pleura and a lung without gross fibrosis, low-pressure artificial pneumothorax will produce complete collapse of the lung. The changes that occur cannot yet be said to be fully understood, but the following may be considered as proved.

1. The pulmonary circulation will be greatly reduced and probably cease, though the bronchial circulation will persist.
2. The lymphatic drainage will be markedly slowed.

3. The bronchial movement and internal movement of the lung tissue is greatly diminished and frequently stopped.
4. There is a relaxation of tension on the lung tissue.

PARALYSIS OF THE DIAPHRAGM

Under similar conditions diaphragm paralysis by evulsing or cutting the phrenic nerve cannot be expected to have the same consequences. The pulmonary circulation and lymphatic drainage will probably not be affected; movement of the lung will be only slightly diminished, and this may be at the apex if the "piston" theory is correct. Relaxation of tension will take place owing to the diminution in size of the thoracic cavity, and this will not occur only at the base. In the operation of lobectomy a comparatively large space is left with a pressure which rapidly becomes negative, but within twenty-four hours the space is obliterated by the lung: this is done by the rest of the lung expanding and "flowing" into it. Similarly, if there is any source of tension in the upper part of the lung, the rise of the diaphragm will allow the lung to "flow" upwards, till a pressure equilibrium is obtained. The importance of the relaxation of tension on damaged tissue is very great. Nature's method of dealing with established tuberculous disease may be said to be: to localize it, to get rid of local organisms and the dead tissue formed, and to repair by fibrous tissue. Repair by fibrosis can only take place with difficulty in a rigid structure or in one under tension, and it is in this last stage of natural healing that the relaxation of tension of damaged lung is so important. If, then, the mechanical sequelae of diaphragm paralysis fall so far short of those of a complete artificial pneumothorax, the therapeutic effects are not likely to be the same, but not for this reason necessarily useless.

A complete artificial pneumothorax will normally check any toxæmia from pulmonary tuberculosis in the collapsed lung in a fairly short time, and unless some accident supervenes the absence of toxæmia will persist indefinitely, even if the patient is doing moderate physical work. The rapid reduction of toxæmia is probably mainly the outcome of the interference with the pulmonary circulation and lymphatic drainage, and not so much of the reduction in movement, as is sometimes thought. In favour of this are:

1. If the lung is collapsed rapidly it is not at all uncommon to find a dramatic reduction of toxæmia in such a short time that it is difficult to understand how it could come about by lack of movement.
2. In cases in which there is much toxæmia selective collapse, even if anatomically successful, is frequently not so therapeutically.

The slowing of the lymphatic drainage may possibly be of therapeutic importance from quite a different point of view if Wingfield's new theory of the causes of relapse is correct. If the drainage is slowed the bronchial glands will have less tubercle bacilli drained into them and hence be given a greater opportunity of settling down and a diminished probability of discharging tubercle bacilli into the blood stream. Aided by the absence of toxæmia the relaxation of tension will help the repair of destroyed lung tissue and probably lead to the formation of a healed scar.

It cannot be expected that such a result will be obtained by paralysis of the diaphragm, as its mechanical effects will not be such as to cause the disappearance of toxæmia. If, however, the diaphragm is paralysed in a case with little or no toxæmia in which the lesion is trying to heal by fibrosis and contraction, the immobile diaphragm will mechanically assist, and possibly turn the scales in favour of sound healing.

A fresh factor, however, is introduced if the patient is put on strict bed rest after phrenic evulsion. This introduces a small proportion of the results (1), (2), and (3) of the artificial pneumothorax, and therapeutically the issue will be similar to that of a complete artificial pneumothorax, though it will be less rapid and efficient. A diaphragm paralysis, then, is unlikely to do away with toxæmia completely if it is uncontrolled by bed rest. In some cases, however, in which toxæmia can be controlled only by rest in bed a diaphragm paralysis may be able, by its relaxation of tension, to promote healing of the lesion while the bed rest holds the toxæmia at bay, with the result that a permanent reduction or abolition of toxæmia results.

A girl, aged 21, was unsuccessfully treated for two months by bed rest for a mid-zone cavity and infiltration. Although the toxæmia was reduced it was not abolished, and x-ray examination showed no improvement. An artificial pneumothorax failed. A phrenic evulsion was performed, and after about a fortnight slight but steady improvement took place, with, finally, complete quiescence and disappearance of the cavity and of tubercle bacilli from the sputum. The diaphragm rise was only $2\frac{1}{2}$ inches after six months, which tends to confirm the presence of adhesions, though they did not apparently interfere with the therapeutic effect.

PLEURAL ADHESIONS

So far I have considered only those cases in which there is a complete freedom from adhesions. The influence of adhesions on cases treated by artificial pneumothorax is well known, ranging from complete frustration of its establishment to no effect in some cases in which the adhesions are thread-like and stretchable. Provided, however, that an artificial pneumothorax of considerable size can be obtained, the question that matters is whether the adhesion is of a type and so situated anatomically as to render impossible the result for which the artificial pneumothorax was induced. For example, in a lung with a dry apical cavity held by adhesions and a spreading toxic lesion in the mid-zone an artificial pneumothorax, complete except at the apex, might have a successful issue for the latter lesion, the adhesions at the apex in no way preventing the object for which the artificial pneumothorax was done. A clear idea, therefore, of just what is to be expected from an artificial pneumothorax will enable us to decide whether or not it has been successful. If not, we can then consider what further steps, such as adhesion cutting, should be taken. This is not a mere debating point, as every physician with experience of this work will have seen many adhesions cut unnecessarily. Speaking generally, the adhesion which calls least for cutting is the easiest to cut.

The question of the exact consequences of pleural adhesions on the results of diaphragm paralysis has not been extensively investigated, as only a pneumothorax or direct vision can demonstrate them. The only work of which I am aware which really has any bearing on this matter is the improvement in collapse brought about by paralysis of the diaphragm subsequent to the induction of a pneumothorax. It seems quite clear that in certain cases in which a pneumothorax is ineffective the phrenic evulsion allows the lung to shrink towards the adhesion, thus relaxing the tension on a cavity or diseased area. The unproved effect of adhesions largely invalidates all work in which estimates of the upward movement of the various parts of the lung are made by calculating the x-ray position of calcified spots before and after diaphragm paralysis. The only general conclusion that can be drawn is that the figures represent the minimum movement in a case with a non-adherent pleura and not extensively fibrosed lung. Again, in most papers the question of the length of time after the paralysis is not taken into consideration.

The part played by adhesions is possibly the cause of the dispute as to the value of diaphragm paralysis, as its detractors probably only use it when an artificial pneumothorax has failed because of adhesions, whereas its champions frequently employ it as a first choice, and thus do so in many cases in which the adhesions are absent or few in number. Taking the extreme case in which there is a complete synthesis between the parietal and visceral pleura, it is evident that no real benefit can be expected. At best, phrenic evulsion can only relieve tensions upwards and then to a slight degree at the extreme base, and can have no effect laterally, because of the thoracic adhesions. If individual adhesions only are present, the result of diaphragm paralysis will depend on their position in the pleural cavity and also on their relation to the lesion it is hoped to control. An adhesion between the lung and the side of the thoracic bony cage will exert a greater influence than a similar adhesion between the lung and the back or front of the cage at the same level, as a larger part of the lung will be free to retract upwards.

The main point, however, which will decide the issue of diaphragm paralysis is the level on the chest wall at which the adhesions are present. If there are adhesions in the diaphragmatic sulcus, the outcome will be similar to that of completely adherent pleurae. If, however, the adhesion is higher the diaphragm paralysis will have an effect on the lung at least up to the level of the adhesion, and probably higher if the adhesions are not very dense—for example, if the paralysed diaphragm is not prevented from affecting a mid-zone lesion by apical adhesions. Again, if a cavity in the upper part of the lung has an adhesion vertically to the apex, there is no reason to suppose that it will prevent a diaphragm paralysis from allowing retraction; but if the adhesion is to the lateral wall considerable interference may take place. Medial adhesions which are not much below the lesion do not seem to do a great deal of harm. The following case will illustrate the point.

A man, aged 28, had an apical cavity about the size of a golf ball, which had been present (without toxic effect) for two years following sanatorium treatment. The upper mediastinum was deflected towards the cavity. Later the cavity began to enlarge and a hæmoptysis occurred. A diaphragm paralysis was performed, and within three months the cavity had closed and the scar was nearly hidden by the mediastinum. The tubercle bacilli previously constantly present in the sputum disappeared.

It would seem, then, that on theoretical grounds a diaphragm paralysis should be useful in any case, including apical lesions, in which a relaxation of tension is required, provided that adhesions do not prevent it. Unfortunately these propositions, put forward on theoretical grounds, are difficult to prove, because they require that an artificial pneumothorax should subsequently be done to show where the adhesions are; but such evidence as exists is in their favour, and my own experience has not revealed cases which disprove it.

Rib resection methods of collapse have not been dealt with: their use depends so much on the technical skill of the operator and exact amount of and position of the ribs removed and their relation to the lesions.

It seems clear, however, that knowledge of the exact effects of collapse therapy is very incomplete, and until further information is at our disposal we shall employ it, to some extent, empirically. The procedures are primarily mechanical and anatomical, and lack of accurate knowledge in these subjects will always lead to inefficiency in results. This does not mean that the knowledge at our disposal should be neglected; and treatment based on a hypothesis which fits in with known facts, even if it is incorrect, is preferable to a "hit or miss" method.

A CASE OF HAEMOCHROMATOSIS

BY

S. WATSON SMITH, M.D., M.R.C.P.Lond., F.R.C.P.Ed.

HONORARY PHYSICIAN

AND

HENRY BLAIR, M.B., B.S.Lond., M.R.C.S., L.R.C.P.

RESIDENT MEDICAL OFFICER

ROYAL VICTORIA AND WEST HANTS HOSPITAL, BOURNEMOUTH

Bronzed diabetes is so uncommon, and this case so unusual, that its publication seems to us to be worth while, particularly because of the absence of diabetes mellitus, the extreme obesity, the deep bronzing of the skin, the atrophoderma of the face, all in a girl of 19 years; and because of the post-mortem findings.

CASE RECORD

A girl, aged 19, single, was admitted to the Royal Victoria and West Hants Hospital on 24/10/31 and discharged relieved on 14/12/31; she was referred by Dr. C. G. H. Morse. The diagnosis made was of suprarenal insufficiency, dyspituitarism, and Addisonian anaemia. The condition on discharge was "improved."

History.—Headache two days previous to admission; went to bed in the afternoon; slept soundly, but could not be wakened next morning. Continued comatose for twenty-four hours, and was then admitted to hospital. There was no evidence whatever that she had taken drugs of any kind. Her past history showed that she had always been large and obese, but grew rather suddenly fatter at the age of about 15 years. She had never menstruated. The mentality before this attack was fairly good; she had won prizes for music when at school.

Examination.—Comatose, but resented interference. Was inclined to throw herself about rather violently if attempts were made to rouse her. Would not, or could not, swallow. There was a large erythematous patch over the right thigh and buttock, with a less distinct patch on the left thigh; the patient was very obese, especially about the hips and thighs. Complexion was dark, skin of face coarse. On admission, temperature 102.5° F., pulse 100, respirations 22. There was no paralysis found in any muscle group; pupils reacted to light; knee-jerks were not obtained; ankle-jerks present; plantar response not definite; abdominal reflexes not obtained; ophthalmoscopic examination not possible. Lumbar puncture, although tried on four separate occasions, failed owing to patient's enormous bulk. The blood pressure was 140/90; the heart was clinically not enlarged; there were no murmurs. Urine: S.G., 1022; neutral; contained some albumin, a few red cells, and a trace of sugar.

Progress.—On 29/10/31 the patient had become conscious and seemed to be mentally unbalanced; gave way to silly laughter at times; erythematous patch on right buttock worse, and inclined to break down; had a loose cough; rales were heard at both bases, especially at the right. The pupils reacted to light and accommodation; no paralyses; muscle power seemed to be rather less on the left than on the right side. There was general dulling of sensation, though not a complete loss. There was no pain to be felt on pinprick. Reflexes as before.

20/11/31.—Pigmentation of skin and hair since admission, similar to that of a mulatto, had now an added jaundice. By the appearance of the abdominal striae there was still a considerable recent laying on of fat subcutaneously. There was no slowing of the pulse, or pruritus, or any abdominal pain, or vomiting. The blood count was now beginning to approach that of an Addisonian anaemia, and confirmed, the halometric reading of 4.3. A continuation of thyroid extract per os was ordered, and one daily dose of adrenaline mix with pituitary extract max was given.

1/12/31.—Atrophoderma reticulata symmetrica faciei, brought about by the too rapid stretching of the skin by overgrowth of subcutaneous tissues and skeleton. Blood cultures and subcultures were negative. 4/12/31: Much better during the past few days; extraction of dental stumps caused considerable bleeding, stopped only with difficulty.

7/12/31: Temperature normal for nearly three weeks now; mental condition fairly good, though a little silly; could get about on her legs quite easily; fit for discharge. On 19/11/31 her blood examination had been as follows: red cells, 2,260,000; leucocytes, 9,700 per c.mm.; haemoglobin, 45 per cent.; colour index, 1.06. The stained blood showed large lymphocytes 10 per cent., small lymphocytes nil, polymorphs 85 per cent., transitional cells 5 per cent.; very slight anisocytosis; halometer reading 4.3. Until 26/11/31 the temperature had been remittent, the diurnal variation being between 98.4° and 103.2°, the pulse rate was 76-110, and the respirations 20-24. The bowels moved each day.

Readmission

The patient was readmitted on 26/9/33 and died on 7/10/33. The history was that she had developed oedema of the legs; that she had felt well until January, 1932, and had then had headaches at night. In February, 1932, she found that she was losing her hair. In April albumin was found in the urine. In August, 1932, her father died suddenly and unexpectedly; he was found to have advanced arteriosclerosis and an unusually small pituitary body and fossa. In December, 1932, she complained of pain in the left side, and in May, 1933, of headaches and giddiness.

Present illness.—For two weeks the patient has had swellings of the ankles and thighs; has had puffy eyes in the mornings, and been excessively tired; she has also been very thirsty and has polyuria, with a nocturnal frequency of 5-6. She has indigestion, with flatulence and heartburn. The bowels are constantly constipated. Sleeps badly and invariably has headaches. No past illnesses.

Examination.—Deeply pigmented generally; obese, especially about hips and thighs; no loss of hair; has a number of vertical linear albinos on each side of the lower abdomen, and many over each hip region and thigh. Bitemporal hemianopia present. Heart: loud first sound at apex and a systolic bruit there. Appearances suggest dyspituitarism. 29/10/33: Disks and whole of retinae are pale in colour. There is marked atrophy of retinal pigment, which in places is gathered into small masses or thin lines lying in front of the retinal vessels. This pigment is in the deeper layers of the retina or in the superficial layers of the choroid. The condition seems more of a pigmentary retinal and choroidal degeneration than an active inflammatory state. On 6/10/33 Mr. Percy Ross reports that the condition of the fundi is unchanged; that the left external field shows a concentric contraction rather more marked on the temporal side, and in the right eye a twenty degree contraction of both temporal and nasal fields.

6/10/33.—Haematemesis of four ounces. Patient states she had haematemesis when an in-patient previously; spleen felt two fingerbreadths below the left costal margin. Pain in left loin, which has become oedematous; perinephric abscess believed to be present there. Temperature now varies between 100.6° and 102.6° F.; pulse, 100-136; respirations, 22; urine shows albumin in small amount, but no sugar, a deposit of many pus cells, some epithelium, many phosphate crystals, no red cells, and no casts. Blood count much as before, but the leucocytes now number 13,000. The fasting blood sugar 0.143 per cent.; bitemporal hemianopia; slight jaundice. On 7/10/33 she had repeated haematemesis, and gradually sank and died.

PATHOLOGIST'S POST-MORTEM REPORT

Dr. C. G. H. Morse, honorary pathologist to the hospital, kindly made an exhaustive post-mortem examination, and reports as follows.

The body is that of a dark-skinned and fat girl, very large and tall for her age. Face, neck, and hands are darker than the rest of the body. Skin generally is deeply bronzed, with pigmentation no more marked in axillae or folds of the skin. There are no localized masses of fat. Facies slightly mongol in type. Neck short, and thick at the base. No thyroid enlargement. Breasts small, nipples indrawn, and areolae deeply pigmented.

Skull.—Hair soft and black. Skin soft, and cuts like that of a child. Nothing abnormal in size or shape of head; calvarium of normal thickness; dura mater normal. There

is slight general oedema of the brain with some excess of cerebro-spinal fluid; no haemorrhage or tumour found. Pituitary gland normal in size. The right frontal sinus contained a calculus about the size of a pea lying loose in otherwise healthy surroundings. No disease of sphenoid, ethmoid, or cavernous sinuses. Cerebral vessels normal. Nasopharynx normal.

Neck and Thorax.—Thyroid gland slightly small for size of patient. Thymus gland not found. There is passive congestion of both lung bases; findings otherwise normal. Some small amount of clear fluid is present in both pleural cavities. The heart is normal in size, the muscle soft and greasy; the endocardium and aortic lining are stained red, and there are two small patches of recent aortitis near the coronary openings. The valves are healthy.

Abdomen.—The abdominal walls are fat. There are many lineae about the lower abdomen and hips; slight amount of clear fluid in peritoneum; no evidence of fat necrosis. Stomach very distended; contains much gas, and a small quantity of grumous fluid and mucus; no source of haematemesis found; intestines distended but otherwise normal.

Liver.—Small, contracted, green in colour, and feels very hard—weight 2 lb. Gall-bladder distended and full of green bile; contains two pigment stones. On section, the whole liver consists of pale yellowish-brown nodular masses in a thick fibrous stroma. The prussian-blue test is very markedly positive.

Kidneys.—Large, soft, and congested. The left kidney has a large perinephric abscess behind it, with one or two ounces of thick creamy pus; no pus found in the kidney itself.

Pancreas.—Quite black in colour and foul-smelling. On section the tissue does not appear diseased apart from the black colour. Prussian-blue test very markedly plus—in fact, rather more so than in the case of the liver. Great distension of splenic vein is present.

Spleen.—Not enlarged, very soft, and rotten.

Suprarenals.—The right cannot be found. The left suprarenal is very friable, and in a mass of fat, but some of it can be removed in pieces. These appear darker in colour than normal. Uterus, tubes, and ovaries are small, and of infantile type.

Microscopical Findings

Liver.—In addition to data already reported, sections of the liver show an active perlobular fibrosis. The interlobular fibrous tissue is very much thickened, and vascularity is increased. Near the external capsule of the organ, which is very thick, many small areas of six or seven cubical cells, resembling liver cells, are to be seen in the fibrous tissue. The cell outlines are indistinct, but the nuclei are clear and granular. Similar groups of cells are also seen in the dense fibrous tissue at the angles of the lobules near the vessels. There are no more than seven cells seen in one group, and such groups have a thin capsule. The liver tissue itself is completely degenerated everywhere. The cells have hardly taken up the stain; no nuclei can be seen. There are masses of fat globules, especially noticeable near the periphery of the lobules. In most of the lobules the central veins are not seen, but one area shows a sclerosed mass in that site, with a few small lymphocytes round it.

Pancreas.—Sections show an advanced fibrosis. The gland cells are atrophied and partly necrotic. No cells can be recognized at all; iron reaction very marked.

Pituitary Body.—Sections show a healthy gland.

Suprarenal (Left).—Sections show normal gland.

Thyroid.—No marked abnormality, except a slight thickening of the interacinar tissue, with some infiltration by small lymphocytes.

Ovary (Right).—Normal ovarian tissue with active ovulation; (This does not conform with the statement that the patient had no menstruation or menstrual symptoms.)

Spleen.—No marked change; passive congestion only.

Kidney.—Advanced cloudy swelling in almost every part. Glomeruli shrunken and cells indistinct. A few tubules only show almost normal structure.

The condition of the pancreas and liver, which are extensively fibrosed and necrotic, show this case to be one of atrophic cirrhosis of the liver. The origin of the condition is, however, obscure. The pathological findings agree with the diagnosis of bronzed diabetes.

DISCUSSION

From all appearances this was a case of bronzed diabetes. In only one specimen of urine was there any sugar to be found, and that simply a trace. With the skin pigmentation of considerable depth and of a definite bronze hue, especially on exposed parts, and with two occasions on which the patient was jaundiced so that the bilious conjunctiva was clearly evident and the cirrhosis of the liver suspected, one could only suppose that the girl, even at her age of 20 years, had died of haemochromatosis. At no time was the liver palpable; it had become shrunken and small, so that one was uncertain about its size on clinical examination. During life, although a provisional diagnosis of haemochromatosis was made, it was not then possible to confirm it; this was done only after the post-mortem examination. The cause and the pathogenesis of the atrophodermia of the face, rare as this condition is, are capable of easy explanation. In the case of this girl the subcutaneous tissues and skeleton increased so rapidly in growth that the skin could not accommodate itself to the increased bulk, and became overstretched, as it did at the same time about hips and thighs. The lesions of the face occurred in the course of two weeks or so, and, pinkish in colour at first, paled after some weeks.

Clinical Memoranda

EFFECTS OF UTERINE CONDITIONS UPON THE BARIUM MEAL: FIBROIDS SIMULATING CARCINOMA COLI

(With Special Plate)

Abnormal conditions of the uterus may at times have curious effects upon the barium meal examination. The following case is submitted as of possible interest in this respect.

The patient, who was in her fifty-sixth year, was on a visit to this country, and sought advice concerning "weakness, anaemia, and constipation," for which, during the previous year, she had been under constant treatment with practically no improvement. From the extreme pallor the anaemia was obvious; but investigation proved it to be of a secondary character. She was still menstruating somewhat profusely and slightly irregularly, but she did not appear to regard these symptoms as of importance, because she "had been accustomed to them all her life." The history of a myomectomy thirteen years previously was then elicited, and one naturally suspected further fibroid growth.

Attempts to carry out an ordinary examination per rectum or per vaginam met with scant success, for the patient at once and involuntarily fell into a state of clonic spasm, doubtless consequent upon an atresia of the vagina, which all operative efforts had failed to relieve. Her marriage, indeed, had never been consummated. Repeated attempts to examine would no doubt have been successful, for the patient was a sensible woman, and anxious to attain some measure of health; but, out of interest in the influence of uterine conditions upon the barium meal, I gave her a small meal, and asked her to return in eight hours. I felt reasonably certain that I should then obtain a radiograph, which would clearly demonstrate the abdominal condition, and which would be of use to me in discussing with the worried relatives the drastic treatment which I had in mind. The result is shown in the illustration (see Special Plate), which presents apparently the characteristic appearances of carcinoma of the bowel, itself a not unlikely diagnosis in this case. Another x-ray photograph was taken twenty-four hours after the meal, and this presents the same appearances, except that the ascending colon is empty, and a few small masses of the meal, roughly a half to one inch in diameter, have found a way into the rectum.

Mr. Aubrey Goodwin operated upon this patient for me a few days later, and removed by hysterectomy a mass of uterine fibroids. To the upper surface and sides of the uterine mass the colon was densely adherent, and was indeed most difficult to separate. This may have been the result of an artificial disposition of the omentum after the previous myomectomy, but, more probably, was due to peritonitis following that operation. There was no evidence of malignant disease either in the bowel or in the uterus. The skiagraphic appearance of colonic obstruction was thus well explained.

The more usual effect of fibroids upon the barium meal is to cause the mass of barium-filled bowels to be borne, as it were, upon an upward curving platform, situated just above the pubis—an appearance that is diagnostic to anyone keeping it in mind.

Radiographic examination in most cases of suspected fibroids would, of course, be a redundant measure; but a case such as has been described may have its value in suggesting the need for a more accurate knowledge of the manner in which the barium meal may be distorted by uterine, tubal, or ovarian conditions. These may well exist unsuspected, and, by complicating a routine barium examination, may give rise occasionally to erroneous and, perhaps, needlessly alarming diagnoses.

PATHOLOGICAL FRACTURE IN GUMMA OF TIBIA

(With Special Plate)

The rarity of the condition in these days and the excellent skiagraphic evidence seem to justify a report on a case of pathological fracture in gumma of the tibia.

An ex-seaman and docker, aged 56, was admitted to Southmead Hospital, Bristol, on February 2nd, 1933. On the anterior surface of his left leg was a large oval ulcer, secondarily infected and foul-smelling. The edge had a "punched-out" appearance, the floor was covered partially by a dirty-looking slough, and bone was felt by a probe through a base of unhealthy granulations. The surrounding tissues showed pigmentation and "tissue-paper" scarring, and the distal part of the leg was markedly cedematous. The whole leg was painful and tender on palpation, owing to its neglected and inflamed state. The right leg showed similar scarring and some superficial ulceration. There was some inguinal adenitis in both groins, but no varicose veins. Further examination revealed nothing of importance beyond signs of neglect and undernutrition, associated with a mild pyrexia and malaise.

The history of the ulceration was vague, but the following was fairly certain. The condition started as a hard lump on the "shin bone" about eighteen months previously, which broke down and ulcerated a few months later. The patient did not consult a doctor, and, during this time (at least twelve months), he had no local or general treatment of any sort. He was out of work, and had recently remained in bed on account of pain in the leg on walking; this was also severe at night. Syphilis was denied. A diagnosis of gumma of the tibia, with possible malignant changes, was made. The patient was given a nourishing diet, and was put on gradually increasing doses of iodides and mercury. Rest and elevation of the limb, with suitable dressings, relieved the pain.

The blood Wassermann reaction was negative. The pathological report on a piece of the edge of the ulcer was as follows. "This is a chronic ulcer. The base is composed of dense fibrous tissue, partly necrotic in places. There is much plasma-cell infiltration, especially around the numerous small vessels. There is no evidence of tubercle or malignancy. The appearances suggest specific disease."

A skiagram of the left leg shows a fairly uniform localized destruction of the middle third of the shaft of the tibia, with several small sequestra in this area. There is dense sclerosis of the surrounding bone, and also subperiosteal new-bone formation. The appearances are characteristic of an inflammatory lesion. Finally, the pathological fracture, with little anatomical displacement and no signs of union, com-

pletes a fairly typical picture of a gumma of bone. This comparatively rare manifestation of syphilis is definitely confirmed by the biopsy, despite the negative Wassermann reaction.

Although there was a marked improvement in the general and local condition of the patient under medical treatment during the following weeks, it was obvious that the ulcer would never heal or the fracture unite owing to the gross sepsis. Amputation was refused, however, until two months after admission, when the leg was amputated above the knee-joint. The stump healed by first intention, and when the patient was seen six months after operation he looked fit and healthy.

I have to thank Dr. A. D. Fraser for the pathological report on the ulcer, and Dr. P. Phillips, medical superintendent of the hospital, for permission to publish this case.

Hospital, Bristol.

LACTATION ASSOCIATED WITH BLEEDING FROM THE BREASTS

In the case described below it was not considered justifiable to excise a piece of the breast for biopsy, especially as in all the reported cases the condition has cleared up. In the absence of further evidence the condition is presumed to be due to an excessive engorgement.

A primipara, aged 29, was admitted a few hours after delivery on September 21st, 1933, to the Leeds Maternity Hospital for severe post-partum haemorrhage. She improved after restorative treatment, including blood transfusion. The next day the baby was put to the breast, and it was noticed that the secretion from both breasts was a dirty brown colour, suggesting the presence of blood. This suggestion was confirmed by a histological report from Dr. Hickman. The patient stated that no blood had come from the breasts previously. Examination revealed no lesion of the nipples and no palpable tumour. Owing to the patient's poor general condition breast feeding was not continued, but a little secretion was exhausted daily while the patient was in hospital. The amount of blood lessened progressively, until on discharge the milk was the colour of weak café au lait. The patient was seen again on November 10th, 1933; the breasts were re-examined, and nothing abnormal was detected. She stated that there had been no milk or blood from the breasts since she left hospital.

Very few cases of this type are to be found in the literature. Fitzwilliams¹ quotes two of those I have been able to find which resemble the present one, and considers the condition to be due to "apparently simple engorgement prior to the establishment of milk." One of the cited cases² was that of a 3-para, aged 26, who had had no abnormality of lactation with previous pregnancies. Oozing from the left nipple occurred during massage one week before the confinement. The right nipple discharged blood after the confinement. No milk appeared till the sixth day, when there were a few drops after oozing of blood from the right breast. The flow of blood ceased from the right breast on the next day. The left breast bled for another week before milk came. Buckle deduces that bleeding from the breast at the end of pregnancy or early in the puerperium need not occasion alarm. It is self-limited, produces no ill effects, and does not call for treatment. The other cited case is that of Habergritz.³ The patient, a primipara, noticed bloodstains on her underlinen near the breasts at about twenty weeks. It continued through pregnancy, and there was also epistaxis on two or three occasions. It ceased two days before labour, but reappeared the day after labour in increased amount. Breast feeding was stopped, as nothing but blood was drawn. The colour of the secretion began to change on the seventh day; by the eighth it resembled ordinary colostrum. The child was put to the breast, and nothing further abnormal was observed. The woman was quite healthy: there was no haemorrhagic diathesis.

Krauss⁴ describes a case in which blood-stained secretion was first noticed to be coming from the breasts during labour. Caesarean section was done for contracted pelvis, and the bleeding persisted until twelve days after the operation, when it gradually disappeared. It is stated that blood came from the upper ducts in the nipple of each side, while colostrum was secreted from the lower ducts. On the sixth day after the operation a small piece was excised from the upper half of one breast for histology. The microscopical picture resembled a "cystofibroma phylloides mammae," which, from the description, appears to be like what we should call an intracanalicular fibroadenoma; there was some diffuse fibrosis of the breast. It is not stated whether there was a palpable nodule at the site of biopsy. Apparently once the blood had disappeared from the milk it did not recur.

A CAUDAL APPENDAGE

Owing to the comparative rarity of this condition the following case of a "tailed" child seems worthy of record.

A male child was born in the City of London Maternity Hospital, under the care of Mr. W. McKim McCullagh, on January 21st, 1934, and weighed 6 lb. 4 oz. It was perfectly normal, except that it possessed a caudal appendage, the attachment of which was midway between the posterior superior iliac spines. The appendage closely resembled a pig's

tail and evidently contained muscle, because a stimulus, such as stroking the buttock, caused the tail to wriggle. X-ray examination showed no evidence of bone.

The question of treatment arose, and it was suggested that the appendage might be left, as its possessor could derive pecuniary benefit in later years as an exhibit in a travelling circus. However, it was felt that the presence of such an abnormality would affect the child psychically, with which view the parents concurred. When the child was five weeks old, therefore, the

appendage was removed under light chloroform anaesthesia, and was found to be attached to the deep fascia by a fibrous band. It measured approximately three inches, and apparently had lengthened in proportion to the child's growth. Recovery was uneventful. There was no history on either side of the family of any similar abnormality, and a previous child was normal.

Reference to the literature shows that a very similar case was reported by M. Errard.¹ The "tail," which was four inches long, was removed. There is no mention as to whether the child could wriggle the tail. B. Chatterton² reports a case which occurred in a male Hindu baby. The "tail" was three to three and a half inches long, and was attached to the base of the sacrum; it enjoyed some degree of movement. The parents in this case refused to consider removal because the fame of the child had begun to spread, and they had already benefited financially.

Reviews

SURGERY OF THE SYMPATHETIC SYSTEM

The publication of a book devoted entirely to the surgery of the sympathetic nervous system is a notable milestone in the history of surgery and also an indication of the great advance which has been made in our knowledge of the subject since Alexander, in 1899, published his experiences in the treatment of epilepsy by cervical sympathectomy. It is well; therefore, that the writing of such a volume,¹ which we believe to be the first in the English language, should have been in the hands of Professor G. E. GASK and Mr. PATERSON ROSS, whose work in this branch is already widely known and accepted. In scope the book covers the whole range of sympathetic surgery, but, quite properly, the main feature is the space devoted to the methods of selecting suitable cases for operation and to descriptions of the various tests which form a part of the pre-operative investigation.

There are, unfortunately, still very wide gaps in our knowledge of the anatomy and especially of the physiology of this system, but the account given by these authors constitutes a very good summary of present ideas. There is a considerable divergency between Continental and English opinions upon some aspects of sympathetic physiology, but although this book very naturally shows a slight English bias the authors have taken a broad view of the whole question, as is well instanced by this quotation from the section upon the highly controversial subject of periarterial sympathectomy:

"At present the trend of surgical opinion in this country is opposed to it, owing largely to the inability of the anatomists and physiologists to reconcile this procedure with the results of their researches, and it has become fashionable to say that the operation has no place in surgery. There is no doubt, however, that in a certain small group of circulatory disorders the operation produces definite improvement, and it is foolish to refuse to recognize the improvement, and to refuse patients the benefit of the operation merely because there is no scientific basis on which to justify the procedure or to explain the results."

In view of the great weight of Continental opinion in accordance with this statement we recognize its wisdom, and its inclusion somehow gives one greater confidence in accepting the claims made elsewhere in the book for other methods, even if their moderation failed alone to do so. Particularly interesting to the operating surgeon is the description of the approaches to the stellate ganglion, for here the authors have evolved a modification of the anterior approach, which they have successfully practised on a number of cases, apparently to the exclusion of the more commonly adopted posterior route as described by Adson. Few will have had sufficient experience of both methods to be in a position to make a competent comparison, but there can be little doubt that the posterior operation is associated with greater loss of blood, the exposure is somewhat more limited, anaesthetization, both local and general, more difficult, and the convalescence rather more prolonged. From the point of view of difficulty or ease of performance there is little to choose, but anyone used to the posterior approach who tries the other method will at least be convinced that it merits much more attention than has been paid to it in the past. In previous anterior approaches, which this replaces, the second dorsal ganglion was often left, and so its contribution to the brachial plexus (nerve of Kuntz) remained; the newer method remedies this deficiency and ensures as complete a removal as the posterior route.

¹ *The Surgery of the Sympathetic Nervous System*. By G. E. Gask, M.G., D.S.O., F.R.C.S., and J. Paterson Ross, M.S., F.R.C.S. London: Baillière, Tindall and Cox, 1934. (Pp. xii + 163; 29 figures, 13 plates. 16s.)

In Raynaud's disease the authors, as a result of post-operative tests, reach the same conclusions as Lewis that the condition is a local arterial one and that a sympathectomy merely lowers the threshold at which the spasm occurs. The vexed question of why the results in the upper limb are less satisfactory than those in the lower is discussed, and the explanation put forward that this is a result of a greater normal vaso-constrictor tone in the lower extremity, and not attributable, as is often assumed, to a less radical operation. The authors, indeed, point out that the cervico-thoracic ganglionectomy is really the more radical operation, since it removes ganglion cells rather than preganglionic fibres; it is equally arguable, however, that the preganglionic fibre has a wider sphere of control than the cell itself, and is therefore the more logical point of attack. In the chapter on the visceral motor system chief attention is devoted to megacolon. A well-balanced account of the anatomical basis of the various operative procedures is given, but this does not suffice to explain why apparently good results are obtainable by so many different methods. Another question of interest is that of a left-sided bias in the supply of the colon; the authors state that "bilateral lumbar ganglionectomy has been carried out with good results, but there is little indication that the removal of the right trunk contributed any appreciable benefit, though on anatomical grounds the bilateral operation must be considered the more rational procedure." With this we agree: there can be no doubt that, whatever the anatomical and morphological considerations, many of the earlier cases in which a left-sided sympathectomy alone was performed gave very good results, which have remained permanent for many years, so that this question must remain *sub judice*. The aetiological relationship of certain types of bladder dysfunction, hydro-ureter, and hydronephrosis to megacolon is recognized, but the need for full investigation before embarking upon operation is perhaps insufficiently stressed. Oft-times a sympathectomy will give good results, but less radical methods of relief are frequently advisable. In any case, it would be futile to expect results from a sympathetic operation where secondary fibrotic changes have occurred.

A final chapter deals with sympathectomy in the relief of pain, and here we find a short but very clear discussion of the cause and treatment of causalgia. Angina pectoris is also considered and the conclusion reached that a cervico-thoracic ganglionectomy is the method of choice, although the only personal experience of the authors appears to be of a paravertebral alcohol injection, after the manner of White. That the injection was successful was indicated by the development of a permanent Horner's syndrome, and the result was freedom from pain up to the time of publication. Altogether we have nothing but praise for this book, which is excellently printed and produced. We congratulate the authors not only upon having written the first English book on the subject, but also upon a very notable contribution to surgical literature.

SHORT HISTORY OF PHYSIOLOGY

The publishers of a new series of short histories have been singularly fortunate in their choice of writers, and in none more so than in the latest volume² to be issued. Dr. K. J. FRANKLIN, a Fellow of Oriel College and the university demonstrator of pharmacology, is a distinguished member of that scientific school which has done so much to establish the reputation of the University of Oxford in this branch of knowledge. In the present little book he has compressed the age-long history of physiology in such

an interesting manner that it has to be read from preface to epilogue, for it is a fascinating story. Beginning with Alcmaeon of Croton, who flourished in the latter half of the sixth century B.C., he passes in review the work of Aristotle, of Erasistratus, and of Galen. Then comes a long interval, during which the work of Galen remained unquestioned until Leonardo da Vinci, Andreas Vesalius, and Michael Servetus overthrew the old teaching and opened up new problems, for they inquired of nature by experiment. The work of Harvey is commented upon, and for some reason Dr. Franklin assumes that he suffered as a young man from gout. Of this there is no evidence, and if Harvey really was laid aside for a time at the university, it is more likely to have been from some form of intermittent fever, then so frequent in Cambridge. Later in life he was gouty, but the gargantuan meals in Germany, when he travelled with the Earl of Arundel, were an all-sufficient cause. Then comes the wonderful period when Willis and Lower, Boyle and Mayow, were working in Oxford; Leeuwenhoek, Swammerdam, and Malpighi abroad. The stream of knowledge never again slackened. Haller and Hunter, by their teaching, Priestley, Lavoisier, and Scheele, by destroying the phlogiston theory, advanced physiology. Finally, there came the work of our own time, which has resulted in physiology becoming, in Dr. Franklin's words, "the experimental study of the normal function of living organisms or of their constituent parts." The book is well adapted to the beginner, for it is written clearly and simply; it is useful to the advanced student, for it shows in an orderly manner the various steps made in the progress of the science. There is a full index of names.

INTRODUCTION TO NEUROLOGY

The only introduction to the study of neurology which is of any real value to the student is a sound knowledge of the essentials of the anatomy and physiology of the nervous system. Until recently the only means the student had of acquiring this necessary groundwork was to search among the standard textbooks for such facts as seemed to be relevant. Here he found himself in two difficulties: the first was that of knowing what to learn and what to omit; the second—which has increased, owing to the recent strides made in neuro-anatomy—that of knowing where to find a summary of the newer work. *An Introduction to the Study of the Nervous System*,² by HEWER and SANDES, combines in outline the necessary basis of topographical anatomy with a balanced summary of the more recent contributions to neurology which have appeared from time to time in various monographs and journals.

The first part opens with a brief account of the different types of neurone and supporting tissues, with an account of the effects of nerve section. Next follows a series of short chapters on fibre tracts, cerebellar connexions, connexions of the corpus striatum, and the autonomic nervous system, together with a description of the blood supply of the brain and a brief account of the cerebro-spinal fluid. This section is not intended as a complete description, for the reader is assumed to be already in possession of the main facts of gross anatomy. Much of the information, therefore, is presented in *précis* form under tabulated headings—an arrangement which, while making for brevity and ease of reference, is apt at times to give rise to ambiguity. An example of this appears in Chapter IX, where "the anterior and posterior cerebral branches of the carotid" are referred to as a part of the circle of

² *A Short History of Physiology*. By K. J. Franklin, D.M. London: J. Bale, Sons and Danielsson, Ltd. (Pp. 122. 3s. 6d. net.)

² *An Introduction to the Study of the Nervous System*. By E. E. Hower, D.Sc., and G. M. Sandes, M.B., F.R.C.S. Second edition. London: William Heinemann Ltd. (Pp. 147; 6s figures. 21s. net.)

Willis. In this part of the book will be found many excellent schematic diagrams in colour, illustrating the course of fibre tracts and the connexions of the various nuclear masses. It is these diagrams, themselves the result of considerable teaching experience, that give the book its distinctive character, and make possible the reduction of the text to a mere 130 pages of letterpress. Few of the usual illustrations are inserted, there being no figure, for example, of the arteries at the base of the brain.

The second half of the book is written from the physiological and clinical standpoint. Here will be found descriptions of the various kinds of sensibility and recent views as to their localization; the clinical effects of interference with motor and sensory tracts at various levels; the features of pyramidal and extrapyramidal rigidity; the role of the autonomic nervous system; and the various causes of aphasia. Though all these chapters are brief they are clearly written, and each section is provided with a short bibliography.

It will be seen from the above outline that this book, while making no claim to completeness, should prove most helpful for supplementary reading, as it furnishes in small compass so much that is apt to be overlooked by the average student.

VACCINE AND SERUM THERAPY

There is certainly room for a volume on vaccine and serum therapy in Churchill's Recent Advances Series, and the new book on this subject is a welcome addition to the set.⁴ It has been written by two authors who have special experience in this type of work. Dr. G. F. PETRIE, who contributes the chapters on serum therapy, is bacteriologist in charge of the Serum Department of the Lister Institute at Elstree, and Professor ALEXANDER FLEMING, the author of the sections on vaccines, is the assistant director of the inoculation department at St. Mary's Hospital, London. The general plan of the book is a consideration of serum and vaccine treatment in different diseases, which are discussed chapter by chapter. This is convenient for reference purposes, and readers can look up such a disease as lobar pneumonia and find what can be done in treatment or prophylaxis by serum and vaccines. Most of the chapters have a good list of references at the end, and the book is carefully documented. There is also a satisfactory index, both for subjects and for authors.

DIET IN HEALTH AND DISEASE

A reliable guide to dietetics for practitioners is at the present time sure of a welcome, and when it comes from the pen of Dr. JOHN D. COMRIE of Edinburgh, the author of Black's *Medical Dictionary*, its popularity can be taken for granted. In his *Diet in Health and Sickness*⁵ the author has aimed at giving precise directions for diets suited to different conditions. The first five chapters deal with the physiology of foods and dietetic principles in a simple, intelligible way, aided by graphic representation of various foodstuffs and their components. The sixth chapter is devoted to the preparation of food, and may have been passed for press before the publication of McCance and Shipp's report on the effects of cooking on flesh foods,⁶ for it speaks of the value of "sealing"

the surface of roast meat and the steaming of fish as if those processes had never been called in question. But the actual cooking directions are admirable, and neither too complicated nor too costly. Incidentally one is inclined to ask if any sane diabetic really eats bran biscuits nowadays.

The chapter on normal diet is short and to the point, and the diagrams showing the calories obtainable by pound weight and sixpennyworth are especially clear. In allowing oatmeal porridge for breakfast every day the cost of cooking is not mentioned, nor is the unsuitability of porridge for some English digestions reckoned with. Margarine is recommended without sufficient indications as to the method of securing that it shall possess either adequate nutritive value or vitamin content. The diets for expectant mothers, infants, and children are good; but, if space had permitted, the author's advice on how to cope with the practical difficulties of feeding abnormal infants would have enhanced the value of this chapter. The last seven chapters deal with diets in particular diseases and disorders. Here the directions are brief, sound, and free from fads or fancies. The author is probably wise to have given particulars of some special diets, such as Salisbury's, Tufnell's, and Gerson's, whose ultimate survival in our armamentarium against disease is already doubtful.

The book is most readably attractive, and contains in small compass many of the directions which the busy practitioner requires, and for which he might search long and vainly in more pretentious volumes.

ESCAPE FROM BOREDOM

When preparing his *Memoirs of a Camp-Follower*⁷ Dr. PHILIP GOSSE had the advantage of a box of letters written by him to his parents from the time he joined the R.A.M.C. in 1914 until the end of the war. He is, by inheritance, a naturalist as well as a writer, and birds and animals form the chief ingredient of his notes. This might have made a dull tale for the ordinary reader, but in fact the only dry thing about the book is the author's humour. One need not be versed in the ways of wild creatures to enjoy it, for there is a quality about the writing that brings reader and writer together. Philip Gosse found solace, amid the horror and the ugliness and the ennui of war, by the exercise of his trained and loving eye for bird and beast and flower. He had also more than a naturalist's eye for the oddities and absurdities of human behaviour, and his journal abounds in crisply told stories, quaint observations, and unexpected asides. From the medical point of view it is full of interest and amusement for those of us who have memories of service abroad as civilian members of the R.A.M.C. Some of the jokes against himself, arising out of collisions or misunderstandings with "authority," might, we suspect, have been told with greater truth, though with less fun, if he had made the other person appear as the butt. There are, however, enough conversations and half-comments to reveal the author's true opinion of the pompous kind of professional soldier and of Poona snobbery in wartime. Towards God's humbler creatures he is uniformly sympathetic and tolerant; though appointed Rat Officer to the Second Army, and energetic in their suppression, he cannot bring himself to write unkindly even about rats. The scene of the larger part of this very human book is laid in Flanders, where Captain Gosse served in and out of the trenches for three years; he was then moved to India, which provided him with a rich harvest of fauna to study.

Notes on Books

Dr. ARTHUR P. NOYES, medical superintendent of Rhode Island State Hospital for Mental Diseases, has written a book entitled *Modern Clinical Psychiatry*,³ which is intended to meet the needs of medical students and practitioners. The volume is an elaboration of a series of lectures delivered by its author to senior medical students who, for the sake of experience, chose to spend their vacation period at the State Hospital. An effort has been made to avoid limiting its presentation to one of description only, but rather to include discussion also of some of the psychobiological forces and processes leading to the clinical pictures that confront the student. The author reveals himself throughout this book as an excellent teacher, and we do not doubt that those students who sacrificed their summer vacation to attend his lectures were amply rewarded.

A useful little book, entitled *A Medical Guide for Trawler Officers*,⁴ has been compiled by Dr. J. BURNS, the medical officer of the Hull Steam Trawlers Insurance

³ *Modern Clinical Psychiatry*. By Arthur P. Noyes, M.D. Philadelphia and London. W. B. Saunders Company 1934. (Pp. 486, 20s. net.)

⁴ *A Medical Guide for Trawler Officers*. By J. Burns, M.B., Ch.B. Issued by the Joint Amalgamated Arbitration and Navigation Committee, St. Andrew's Dock, Hull. (Pp. 124; illustrated.)

and Protecting Co., Ltd. The book is a guide in first aid for injuries and the elementary diagnosis and treatment of the diseases most commonly to be met with in trawlers at sea. These Hull trawlers are equipped with a standard first-aid outfit and medicine chest, and Dr. Burns explains how the best use can be got out of both of these very necessary articles. The opening sections of the book explain such elementary details of anatomy and physiology as are absolutely necessary for the understanding of the subsequent chapters on injuries and sickness and the proper application of the methods recommended for dealing with them. The book is admirably practical, and should be of the greatest assistance to trawler skippers and mates when they find themselves up against medical problems and have the sole responsibility for deciding what has got to be done about it.

The numerical summary in the *Medical and Dental Students' Register*⁵ for 1933 shows that 2,287 medical students registered last year, representing an increase of 340 over the figure for 1932, and of 644 over that for 1931; the entry was, in fact, by far the largest recorded during the past thirteen years. The number of dental students registered in 1933 was 383, an advance of 61 over the figure for the previous year, and the largest entry since 1920.

Preparations and Appliances

TROCAR AND CANNULA FOR INJECTION TREATMENT OF HYDROCELE

Mr. RODNEY MAINGOT, F.R.C.S. (London, W.), writes:

There are numerous types of trocar and cannula used for tapping hydroceles, but the one which I have had specially adapted for my own use has proved both practical and satisfactory. It consists of a trocar and cannula, made in two sizes (the large size equal to a 10 S.W. gauge, and the small size equal to a 12 S.W. gauge), and a rubber connexion piece with special bayonet-fitting mount.

The trocar and cannula is introduced into the hydrocele sac, and the finger-piece is firmly grasped between the thumb and index finger of the left hand. The trocar is then withdrawn. After all the fluid in the hydrocele sac has been evacuated a 10 c.m. syringe is charged with a suitable solution and

attached to the cannula by means of the rubber connexion. This connecting piece allows of a certain amount of flexibility in the manipulation of the syringe during the process of injection. At the completion of the injection the cannula is removed and the parts are massaged.

This trocar and cannula is made for me by Arnold and Sons (John Bell and Croyden), 52, Wigmore Street, London, W.1.

FLOOD-LIGHTING THE BLADDER

Mr. CLIFFORD MORSON, F.R.C.S. (London, W.), writes:

The technique for prostatectomy introduced by Harry Harris of Sydney, Australia, requires perfect illumination of the bladder. For the past six years I have used a special retractor which overcomes certain difficulties common to all vesical operations.

First, the blades are fenestrated so that a minimum of mucous membrane is covered when the retractor is in position.

Secondly, they are so shaped that the abdominal wall as well as the bladder is retracted. Thirdly, they are of different sizes to meet the difficulties of alterations in depth of the bladder within the bony pelvis. Fourthly, the blade which holds back the postero-superior wall is so curved that the part immediately behind the interureteric bar is also retracted. Lastly, as the result of my adoption of the Harris technique for prostatectomy, Mr. Schranz of the Genito-Urinary Manu-

facturing Company has electrified this retractor so that it flood-lights every nook and corner of the bladder as well as the prostatic bed, after removal of the prostate.

The accompanying illustration shows quite clearly how ingenious Mr. Schranz has been in adapting this retractor for flood-lighting purposes. It will be noted that the lamps are situated at different levels within the bladder, and that the wiring is cleverly concealed. The whole instrument can be boiled without endangering the efficiency of the electrical equipment.

HOSPITAL ADMINISTRATION AND THE LOCAL GOVERNMENT ACT

DR. ALLEN DALEY'S REVIEW

The problems in hospital administration arising out of the Local Government Act, 1929, were the subject of a paper read by Dr. W. Allen Daley, Principal Medical Officer, London County Council, at a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine. The president of the Section, Dr. J. D. Rolleston, took the chair.

Dr. ALLEN DALEY said that it was now nearly four years since the county and county borough authorities in this country became responsible for the public hospital provision in their areas, and enough time had elapsed to consider the position and review successes and failures. The dovetailing of public medical services under the Local Government Act had proved no easy matter, and it would be some years yet before the process could be regarded as complete, even in the most progressive areas. There were advantages and disadvantages in the "appropriation" of hospitals. From the point of view of the patient the great advantage of appropriation was that he could be admitted simply by application to the medical superintendent; he had no need to apply to the relieving officer, which was the normal method of admission to a Poor Law institution. The appropriated hospital was free from the hampering restrictions of the Public Assistance Order. The most important point on the reverse side concerned the recovery of the cost of treatment of extra-district patients. Safeguards for this were provided in the Poor Law, but in the case of appropriated hospitals the legal position was by no means clear.

MUNICIPAL HOSPITAL SERVICES

The administration of a municipal general hospital service brought many new problems. The first was as to the amount and nature of hospital accommodation necessary in an area. The number of hospital beds per 1,000 of population varied enormously. For example, including the mental hospitals, the total hospital beds in England and Wales per 1,000 of population was 9.47, while in London it was 19. Up to a point which could not be determined with any accuracy, the demand for admission to hospital tended to grow with the provision of satisfactory accommodation. Such factors as domestic overcrowding, incidence of endemic and occupational diseases, and the liability to road accidents in the locality of the hospital had to be borne in mind in assessing the needs of an area. In London and the large cities and urbanized portions of county areas much could be done to provide special hospitals and special units in general hospitals which would be quite impossible in small towns or rural counties. Examples of such special units were children's country hospitals for prolonged treatment, hospitals for chronic skin or eye diseases, colonies for the epileptic, and convalescent homes. Special units might be required in only one of a series of hospitals where particular skill was needed on the medical or surgical side, or where equipment was very costly; examples were plastic surgery, the treatment of chronic rheumatism, and deep x-ray or radium therapy. Other special units such as maternity, tuberculosis, or venereal diseases wards and mental observation units were required for groups of hospitals. There could be no uniformity for many reasons, one reason of great importance being the varying provision of voluntary hospitals in the neighbourhood. There should be the fullest consultation on both sides as between the voluntary and municipal institutions. In London some very useful work had been done in the shape of two surveys, one of voluntary and the other of municipal hospital accommodation.

A general impression obtained some years ago that while voluntary hospitals had large waiting lists, Poor

Law hospitals always had large numbers of empty beds. The former statement was true, but the position in the municipal hospitals required explanation. A voluntary hospital could decline to accept any patient; a municipal hospital must admit on demand those who were medically destitute, including those sent on from a voluntary hospital. There were high and low tides of disease, and the municipal hospital had to be prepared for the high tide. In the months January to March the municipal hospitals were sorely pressed for room, and only in the summer months was there surplus accommodation. In certain towns, particularly where the honorary staff of the voluntary hospital were attached to the municipal hospital, the municipal hospital at periods of great demand dealt with patients on the waiting list of the voluntary hospital. As for out-patient departments, it would be a mistake for the municipal hospital to develop these on the lines of the voluntary hospital, and the London County Council set out the types of patients dealt with in its out-patient departments as follows: (1) casualties, accidents, and other emergencies; (2) continuation or after-care of former in-patients requiring further treatment after discharge; (3) patients referred for consultation by any duly authorized medical officer of the council; (4) patients requiring ante-natal or post-natal examination and treatment; (5) patients entitled to outdoor medical relief; (6) cases or classes of cases for special examination with or without treatment, authorized by the council's medical officer.

PRACTICAL PROBLEMS FOR SOLUTION

Dr. Daley touched briefly on other matters arising out of the change in administrative control. In many areas it was found that there was no definite relationship between the district medical officer and the medical superintendent. Closer co-operation was most desirable. A considerable number of residential Poor Law schools were transferred, and these brought with them their own problem. The best method of controlling infection, whether by quarantine blocks or by other methods, had not yet been finally settled. The transferred hospital service presented a great field for investigation and research. Cases could now be followed through and clinical research undertaken. In the largest authorities the opportunities for investigation afforded very wide scope. Investigation could be carried out on types of hospital building. He did not believe that the ideal ward block had yet been designed. There were hundreds of points in the design and structure of a hospital on which there was no authoritative opinion. The standardization of equipment and mass purchasing was important. In London before 1930 there were twenty-six different standards and as many different sets of contracts for hospitals. An illuminating sidelight was afforded by a study of costing returns. Laundry statistics, for example, showed that the total cost of laundry per occupied bed in different hospitals varied from 2s. 8d. to 5s. 3d. per week, and the cost per 1,000 articles washed from £2 7s. 4d. to more than double that amount. The same wide variations were found in crockery breakages. The breakages of teacups varied from 36 per 100 residents over a period of six months to 257. The cost of staff dietary varied per 100 boarded staff per week from £30 5s. 11d. to £44 16s. 4d. Another point was the training of medical superintendents. In a large hospital the medical superintendents might be almost entirely engaged in administrative work, but if provided with lay assistance they could still take part in some clinical work. It was wasteful to train a man to be an expert clinician or operating surgeon and then employ him almost entirely administratively, but there was a tendency for this to happen where the administrative officers were remunerated much more highly than the clinical. Facilities for pathological investigation were essential, and the London County Council had provided five group laboratories and a central histological laboratory, in addition to the small laboratories attached to individual hospitals. Each medical school in London was now linked up with one or more of the municipal general

hospitals. Classes of post-graduates were also held, and there were clinical demonstrations attended by general practitioners. At various units there was provision for clinical research, and statistical research was now being carried out on a large scale. In the case of each of the 200,000 patients admitted to London County Council hospitals in the course of a year, the essential features were recorded, and a method of mechanical tabulation had been worked out.

THE LOCAL GOVERNMENT ACT AND PREVENTIVE MEDICINE

The Local Government Act, Dr. Daley said in conclusion, was already having a marked effect on the progress of preventive medicine. Curative medicine was often regarded as a more attractive study than preventive. The triumphs of preventive medicine were unknown to all save the few. An arrested epidemic did not stir public opinion. There was a danger in the present situation lest they became so immersed in the fascinating problems of administering hospitals and curing disease as to forget that the primary function was to preserve health and prevent disease. He believed that some tangible results affecting the great problem of preventable disease would presently appear, and then the work of the framers of the Local Government Act would be fully justified. At present those concerned were in the process of moulding a large additional service on to the general public health service of the community; in some areas the addition was much larger than the original. Dr. Daley circulated an analysis of records of four large general hospitals, showing in five principal age groups of life the treatments given in different disease groups, the results obtained, the duration of treatment, and the approximate cost. These figures showed that the most expensive disease group was the respiratory (bronchitis, pneumonia, and pleurisy), followed after a long interval by injuries, close behind which came tuberculosis and venereal diseases as a single group, and diseases of the nervous system as another group. The duration of treatment for diseases of the respiratory system was 14.1 per cent. of the total for all diseases; for injuries, it was 10.6 per cent.; for tuberculosis and venereal diseases, 10.4 per cent.; and for diseases of the circulatory system, 9.9 per cent.

GENERAL DISCUSSION

Dr. J. D. ROLLESTON said that Dr. Daley had not emphasized the important work he himself had done in connexion with the transferred and special hospitals. He had been chairman of no fewer than eight of the ten Departmental Committees on the subject—namely, those on hospital standards, tuberculosis, pathological laboratories, forms of record, ambulance service, staffing of transferred hospitals, appointment of junior medical officers, and district work.

Dr. S. MONCKTON COREMAN, a member of the new London County Council, said that in a short period of time the amount of hospital accommodation had not only been largely increased, but the accommodation and treatment in every possible way greatly improved. Although the number of separate institutions was not much greater, there had been an increase in accommodation, he believed, amounting to some thousands of beds. The linking up with the voluntary hospitals was an excellent idea, in order that the students could be definitely instructed by their own teachers in the wards of the municipal hospitals. He also mentioned that during the past year more than one-sixth of the total number of parturient women in London had been delivered in the municipal hospitals; this provision, in conjunction with the special laboratory work now proceeding, must have an effect in reducing the maternal morbidity and mortality rate.

Mr. A. F. MACCALLAN said that it struck him that it was rather difficult for a physician or surgeon to teach on other people's cases unless he had had considerable opportunity of examining the cases beforehand. Few of them had time for such study, even with the greatest

courtesy on the part of the medical superintendent and his staff, and therefore it did not seem to him that very satisfactory demonstrations could be given to students in these circumstances. That was a difficulty in linking up council with voluntary hospitals for teaching purposes.

Dr. J. A. H. BRINCKER claimed for the old Poor Law hospitals and the guardians that in addition to looking after sick persons they had an eye to the development of preventive medicine, and that preventive medicine originated with Poor Law officers and their hospitals. The Local Government Act was admirable in its working so far as London was concerned, because of the enormous number of institutions, but the position was not so easy in small areas.

Sir WELDON DALRYMPLE-CHAMPNEYS said that on a few occasions he had had the pleasure of serving on the Hospitals Standards Committee of the London County Council, and he had been astonished that nothing so comprehensive had ever been attempted before. A great saving could be effected by the standardization of equipment and by combined purchase. It would be interesting to know what Dr. Daley thought of the prospects of the system being applied to voluntary hospitals. The chief difficulty was that the surgeon, for example, got accustomed to various types of instruments, and was a little resentful when new instruments were presented to him. At the same time he thought the standardization of equipment had to come.

Dr. C. T. MAITLAND (Ministry of Health) said that naturally the bias of the paper was London; in the counties some of these things assumed different values. He thought that the main result of the Local Government Act was not so much the breaking up of the Poor Law as the opportunity which it gave to local authorities when they found themselves presented with hospital accommodation, from whatever source, to examine the whole question of general hospital treatment.

Dr. A. M. HEWAT (London County Council) expressed his gratification at the emphasis which had been laid on preventive medicine. The hospital administrator was apt often to lose sight of the preventive aspect. With a large hospital service one ought to be in a position to develop preventive medicine in a way in which it had never been developed before. A vast supply of information was accumulated on various points connected with different diseases and different classes of patients, and if this was dealt with properly and the information tabulated, a different outlook ought to be possible on the preventive side of many diseases.

Dr. F. C. SHRUBSALL said that as one who saw patients after they had passed through hospital he had noticed a remarkable psychological change since the new system came into being. A few years ago there was a feeling of terror among patients at the prospect of going into a Poor Law hospital (though not because they had any anticipation of being badly treated), but now he was often told that they would rather go into a council than into a voluntary hospital, because "the meals are served in a much more human fashion." Dr. ALEXANDER JOE remarked that now that medical officers of health throughout the country were being confronted with these big problems of hospital administration, it seemed to him that there might in the future be given a certain impetus to the theories put forward by Simon of Manchester, that the days of the medical officer of health were passing, and in the future there might be a lay officer of health. A great deal of the purely administrative work was almost entirely lay. Dr. E. W. GOODALL gave certain amusing experiences of investigation into wastage and breakages in hospitals.

Dr. ALLEN DALEY, in reply, said that in the work at the County Hall the departmental committees had been most valuable. Since April 1st, 1930, the council had increased the number of hospital beds by 2,000, and two extra hospitals had been brought into use. Maternity admissions were going up at the rate of 1,000 a year in the County of London. It was the council's policy to provide a hospital laboratory in every "acute" general hospital, and these were worked in association with the group laboratories.

AMOEBC DYSENTERY

THE OUTBREAK IN CHICAGO

(FROM A CORRESPONDENT)

So many conflicting reports of the now well-known outbreak of amoebic infection which commenced in Chicago on August 16th last year have been made that it is a relief to have published by those most directly concerned with it the actual sequence of events. Briefly what happened was this. On August 16th two cases of amoebic dysentery were notified from two hospitals. Inquiry showed that both the patients had fed at a certain hotel where cases of diarrhoea were found to have occurred. On the following day a laboratory was established in the hotel, and "stools from all the food-handlers were collected and examined, under the supervision of trained technicians who were experienced in the diagnosis of amoebiasis." The result was that, by the end of the month, fifteen clinical cases (we are not told if these were actual cases of dysentery) and eleven carriers were discovered among 364 food-handlers, a percentage of about 7.1. The situation was watched during September, and no new cases arose which could not be attributable to earlier infection.

PUBLIC HEALTH MEETING AT INDIANAPOLIS

On October 9th attention was called to this incident at the annual convention of the American Public Health Association in Indianapolis. It was given publicity in the local press, with the result that on the same day it was brought to light that two members of a family in Indianapolis had been affected with amoebic dysentery after a visit to the hotel in Chicago. Further inquiry in this city disclosed a total of eight such cases. This discovery, and the appearance of some new cases at the hotel, led to the institution of further examination of the staff and the dispatch of a questionnaire to 16,000 persons who had stayed at the hotel during June, July, and August, 1933. This last inquiry, which was followed up by long-distance telephone or telegram urging immediate medical care for those afflicted, resulted by November 8th in the discovery of thirty-five cases of "diarrhoeal disturbance" among those 16,000 guests who had stayed at the hotel.

"It was then decided that the situation was sufficiently serious to justify the issue of a general warning to the Press." This was carried out on November 9th, and again on November 10th, while on November 14th a special broadcast was made over the N.B.C. network from coast to coast and in Canada, with an appeal to those suffering from intestinal disorder to see their doctors, and to physicians to be on the look out for amoebic dysentery."

INVESTIGATION OF FOOD AND WATER

The second examination of the food-handlers at the hotel, completed by the middle of November, revealed the fact that, though those detected at the first examination had been removed, others were found to be infected who had not been so at first. It was therefore concluded that the control of food was not checking the infection. Examination of the water supply was then undertaken, and it was found that there were serious defects which might permit of the contamination by sewage of food and drinking-water. Another hotel is now mentioned in which a very serious condition of the water system was discovered, and in which a high incidence of amoebic infection also occurred. Finally, it is stated that in the hotel first considered five surveys of food-handlers and two surveys of non-food-handlers had been completed by the end of January. The result was the discovery of infection in 165 food-handlers and in 141 non-food-handlers out of approximately 1,100 employees. Exact

details of these examinations are not given, but it may be presumed that the food-handlers found to be infected at any time were at once removed and replaced by others, but we are not told if the latter were known to be uninfected individuals. Furthermore, we do not know if the well-attested fact was recognized that, owing to the intermittency of the appearance of cysts in the stool, a single examination of a group of people yielded a number of carriers which is only about one-third of those which can be discovered by repeated examination.

The broadcast mentioned above resulted in the report of 721 clinical cases of amoebic dysentery in 206 cities, including Chicago, as apparently originating from the same source. In addition, 1,049 carriers of *E. histolytica* were brought to light in Chicago, presumably in places other than the two hotels, by the investigations. A general laboratory survey of all the principal hotels and larger restaurants was also made, but no parallel to that of the two original foci could be found, though it is reported that in an industrial plant in Chicago employing 375 workers a connexion allowing river water to contaminate the water supply was made in December. This was followed shortly after by an outbreak of diarrhoea. Investigation by the Board of Health revealed seven cases of amoebic dysentery, seventy-one carriers of *E. histolytica*, and three cases of typhoid fever.

REPORT OF THE SPECIAL COMMITTEE

The interest taken in the infection was so great that the President of the Board of Health eventually appointed a special committee to examine the situation, and it met in Chicago from January 22nd to 26th inclusive. It reports that until 1933 amoebic dysentery had not figured largely in the morbidity and mortality reports in Chicago, or indeed in any city in the United States. The outbreak in 1933 embraced about 800 reported cases, most of which became apparent in cities other than Chicago. A large majority of these were traced to two hotels as probable sources of infection. The report says that the unprecedented nature of the outbreak must be borne in mind, for until this time amoebic dysentery had not been known to occur as an epidemic disease in a civil population. Though this is the case, the examination of the records and laboratory materials, preparations, and cultures led the committee to the view that the cases diagnosed as infected with *E. histolytica* were actually of this nature.

It is noted that the examinations (presumably single ones, and not repeated ones as made at the hotel) carried out have shown that 3.9 per cent. of employees in hotels and restaurants in general in Chicago are carriers of *E. histolytica* or suffer from amoebic dysentery—an incidence which is about equal to that among the population of the United States in general. In the hotel first examined the percentage of infection among the employees was at times as high as 18 per cent., that among the food-handlers being approximately the same as that among those with other duties. This fact suggested that structural defects, either permanently or intermittently operative in the two hotels, were associated with an unusual incidence of amoebiasis. Such defects, the committee states, no doubt exist in other hotels, but only special circumstances bring them into play to cause a severe epidemic. Such special circumstances are necessary, for it is known, the report says, that extremely large doses of *E. histolytica* have to be administered to both man and animals to produce infections comparable with those observed in this epidemic, in which the incubation period was short, the lesions were severe, and the exposure often minimal.

DO AMOEBIASIS EPIDEMICS OCCUR?

The above reports raise once again the whole question of the method of spread of *Entamoeba histolytica* and

of whether actual epidemics of amoebiasis arise. At the commencement of the war it was thought that amoebiasis was accounting for practically the whole of the invaliding from Gallipoli. This was due not only to lack of experience in the diagnosis of intestinal protozoal infections, which is notoriously difficult, but also to a misconception regarding amoebiasis on the part of those handling the cases. They considered it an acute infectious disease like cholera or bacillary dysentery, whereas actual amoebic dysentery is rather the periodic dysenteric manifestation of a chronic amoebic infection. It seems not improbable that the actual dysentery is caused or stimulated by some intercurrent bacterial infection, or other irritant, acting in a carrier, so that one is led to wonder, in the incident recorded above, whether, assuming that the diagnosis was correct, the occurrence of two cases of amoebic dysentery on one day in persons who had fed (we are not told when) at the same hotel is sufficient justification for the assumption that the amoebic infection had actually been acquired there. Even though inquiry had elicited the fact that there were cases of diarrhoea at the hotel, the immediate establishment of a laboratory there appears to indicate that amoebic dysentery was being looked upon as an acute infection apt to spread rapidly. Such a procedure is perhaps surprising to those who, from a long experience of the disease and its diagnosis, both in the Tropics and in more temperate climates, have never observed that amoebiasis spreads rapidly, in epidemic form from case to case. One is also led to wonder how in a city like Chicago, where amoebiasis is said to have appeared so rarely in the past, it was possible to find, at such short notice, technicians with the necessary experience to carry out the examinations accurately. The laboratory nevertheless returned a high percentage (7.1) of carriers of *E. histolytica* in this hotel, and later in another hotel and in an industrial plant; finally, 3.9 per cent. of carriers were detected among employees of other hotels and restaurants in Chicago. Allowing for the fact that the repeated examinations at the first hotel were bound to yield a higher percentage of carriers than the fewer examinations of employees at other places, it seems clear that the action taken, whether justified or not by the circumstances, has revealed a widespread carrier condition in the city—so much so, that there is some ground for asking whether some of the individuals who were supposed to have been infected in the two hotels may not already have been carriers before coming to Chicago, while others may have become so at other places in the city, where, in the warm season, they must undoubtedly have taken food and drink outside their hotels. It is notorious that, under the conditions of tourism, diarrhoeic disturbances are far from uncommon.

A SUGGESTION

From all that is known of experimental infection and the dosage of cysts required to produce it, it is difficult to imagine any form of contamination of food or water with faecal matter, even when direct connexions exist between the water supply and sewage system, which will allow people complacently to ingest the enormous doses of cysts required to cause amoebic dysentery, and to lead to the development of amoebic infections to the extent they are supposed to have done after very short incubation periods, which in some cases, we are privately informed, were not more than two days.

On the other hand, bacterial infections, or food poisoning, or other intestinal irritants, may light up amoebic infections or even give rise in carriers to dysenteric symptoms. Therefore, though infections were undoubtedly taking place in the hotels examined to an undetermined extent, as well as in other parts of the city and in the United States generally, it would appear from the data available hardly necessary to revise our

conception of amoebiasis in the direction of looking upon it as an alarming disease demanding immediate preventive measures such as are necessitated by sudden and unexpected outbreaks of cholera, bacillary dysentery, or food poisoning. A possible explanation of the outbreak is that the immediate action taken, and the publicity given to it, aroused interest in an incident which otherwise would have passed unnoticed, and brought to light a condition of affairs in Chicago which had been in existence for a considerable time.

AUSTRALASIAN MEDICAL CONGRESS

FOURTH SESSION, HOBART, 1934

The fourth session of the Australasian Medical Congress (British Medical Association) was held at Hobart, Tasmania, from January 15th to 20th, some 300 members attending. The Patrons of the Congress were: the Governor-General of Australia and the Governor-General of New Zealand; the Governors of New South Wales, Queensland, South Australia, and Tasmania; the Lieutenant-Governors of Victoria, Western Australia, and the Territory of Papua; the Director of Education and the Premier of Tasmania; and the Mayor of Hobart. The president of the Congress was Dr. D. H. E. Lines.

The inaugural meeting, which was held in the town hall on January 14th, was opened by Sir Ernest Clark, Governor of Tasmania. The following message from the parent body of the British Medical Association was read:

"The parent body regrets its inability to appoint a delegate to the Australasian Medical Congress, but sends cordial greetings and best wishes for a successful session."

PRESIDENT'S ADDRESS

Among the subjects of special interest to the profession generally to which Dr. Lines referred in his presidential address were abortion, the education of the public in health matters, and the medical curriculum. Discussing abortion, he said that more women died in Europe after abortion than after parturition at full term. No penalties would prevent a desperate woman from taking any risks to get rid of a child she did not want to bear. Many thoughtful people were beginning to realize that something should be done, and that the indications for abortion should be extended. Dr. Lines emphasized the need for education of the public in health matters. The lay press, he said, could be of inestimable assistance; unfortunately, articles on health in certain newspapers were more often written by persons having no proper knowledge of the subject with which they were attempting to deal. Referring to the medical curriculum, Dr. Lines said there was an uneasy feeling abroad that the modern medical student was so crammed with facts and theories that he had no time for independent thought. It was being said that the present system aimed at making students "a kind of cell-colony of half-baked specialists and scientists." The medical student was unable effectively to use the knowledge he had laboriously acquired; he had a pathetic belief in the ability of laboratory procedures—which he was unable properly to perform himself—to solve his problems.

At the conclusion of the inaugural meeting the president held a reception at the Tasmanian Museum.

CANCER RESEARCH

On January 16th there was a full meeting of Congress for the discussion of the cancer problem. Papers dealing with various aspects were read by Drs. F. P. Sanders, J. H. L. Cumpston, H. G. Chapman, J. V. J. Dubig, L. J. Clendinnen, and E. H. Molesworth. The following resolution was carried:

"That in the opinion of this Congress the time has arrived for a more active co-operation between Governments, medical organizations, scientific bodies, and the general public, in the prosecution of the Australian campaign against cancer."

At a full meeting on January 18th hospital problems were discussed, representatives of every State taking part. No resolution was carried.

MEETINGS OF SECTIONS

The following Sections held meetings each day during the session: Anaesthetics; Medicine; Naval, Military, and Air Force Medicine and Surgery; Obstetrics and Gynaecology; Ophthalmology; Oto-rhino-laryngology; Paediatrics; Pathology, Bacteriology, and Cancer Research; Public Health, Preventive Medicine, and Tropical Hygiene; Surgery; and X-Ray and Electrical Therapy. Among the many important subjects on which papers were read were: the microcytic anaemias; renal function tests; the source of muscle tone; prophylaxis of uterine cancer; endocrines and eye diseases; health of the child in pre-school and school age; tuberculosis in school children; and new evidence of relationship of cancer and tuberculosis.

SOCIAL EVENTS

On January 15th Sir Ernest Clark entertained the members of Congress and their wives at a garden party at Government House, Hobart. On the following day a mayoral reception was held at the City Hall, which was followed by a dance given by the members of the Tasmanian Branch of the British Medical Association. Various entertainments and excursions were arranged for the visiting ladies. A ladies' golf competition was held, also a competition for the Australasian Medical Congress (British Medical Association) Golf Cup, open to all members. The cup was won by Dr. G. C. Scantlebury, Melbourne.

Throughout the session cordial hospitality was extended to visitors by the members of the Tasmanian Branch, which was greatly appreciated.

SMOKE IN THE ATMOSPHERE

A LANCASHIRE STUDY

The town of Rochdale, as everyone knows, is situated in Lancashire, north-easterly from Manchester. It stands at an elevation of 475 feet, close up to the Pennine Range, and experiences a copious rainfall. Its population of 90,000 reside in 26,000 houses, mostly equipped with open fireplaces for the burning of bituminous coal. Its cotton mills, which derive their power from steam, discharge furnace smoke freely. These local sources liberate their smoke into air already polluted, for owing to the prevailing winds the town lies in the direct track of the smoke drift from what is perhaps the most densely industrialized district in Britain. Through the combined effect of these various forces the atmosphere of Rochdale provides an unrivalled field for smoke observation. Records were begun in 1916, and have been carried out on a systematic plan since 1927. Dr. J. R. Ashworth, in a book recently published,¹ sets forth some results of the investigations made, and usefully describes new forms of apparatus devised for the solution of special problems arising. Among these may be mentioned the twin atmosphere pollution gauge for determining the amount of impurity carried into and out of a given area; and the horizontal pollution gauge, which deals with the material borne along by the wind, as distinguished from that thrown down as deposit.

SOLUBLE AND INSOLUBLE DEPOSITS

The author finds that in industrial towns the insoluble precipitated matter in the deposit gauge is high, diminishing rapidly from the polluting centre outwards. Being composed largely of flue dust from factory chimneys, it is heavy and quickly falls. It is most in evidence in dry weather. The soluble deposit, which is lighter, carries further, and is in consequence more evenly distributed. Its amount is largest with high rainfall. Much tar is the special indicator of domestic smoke. The proportion of

the deposit from factory chimneys and domestic fires varies in different towns, but is given on average as half-and-half. The horizontal pollution gauge at Rochdale revealed that the impurity carried along by the wind was about six times the quantity deposited; also that the amount of wind-borne soluble matter was relatively large. The horizontal gauge, in the author's view, gives results which are nearer the truth than those of the deposit gauge.

SMOKE AND RAINFALL

Employing the daily deposit recorder, Dr. Ashworth observed that rain always brought down atmospheric impurities, but that this effect might be more than balanced by the laying of dust, which prevented particles from rising into the atmosphere. The effect of snow in precipitating solids was immediate and very marked. The automatic filter for determining the amount of suspended matter in the air revealed that smoke haze, with attendant diminution of light, was more frequent on Mondays than on other days of the week. This phenomenon is ascribed to greater household activities on that day, and the author adduces in partial confirmation the records of a group of mainly all-electric council houses where the maximum power for washing, drying, and ironing was consumed on Mondays and Tuesdays.

That smoke should favour the formation of water drops, and so conduce to rainfall, is likely not only by reason of the number of hygroscopic particles which it carries, but also owing to the quantity of combustion-derived water vapour which it launches on the air. The observations of rainfall at Rochdale over a period of thirty years fit in well with this hypothesis. Sunday, when the emission of factory smoke was least, emerged as the driest day of the week. Monday, when the boilers were being heavily fired for reheating after the repose of Sunday, was the rainiest day. It is noted, too, that the rate-of-rainfall curve and the rate-of-soot-fall curve tended to vary in the same direction. The increase of soot, the author concludes, is the cause and not the effect of the heavier rain.

INFLUENCE OF ATMOSPHERIC POLLUTION ON LIGHT

The closing section deals with the influence of atmospheric pollution on light as determined by the iodine method, the acetone methylene-blue method, and the photographic method, of which the two former do not distinguish the ultra-violet from the visible rays, while the last enables account to be taken of the ultra-violet rays alone. With the iodine method it was found that, year in year out, the light received in the city area of Manchester was only about 53 per cent. of the light at suburban Timperley. With the acetone methylene-blue method the observations published by the Sunlight League show St. Ives at the head of the list with an annual average value of 5.34 for effective radiation, while Torquay stands at 3.64, Bristol at 2.35, St. Andrews at 1.98, Larnie at 1.62, and Southend at 1.21. These results are, within limits, comparable, but much depends on latitude, and a good deal on dexterous siting of the test apparatus. With the photographic method it was demonstrated that during January, 1931, a part of Rochdale where the factories cluster received nearly every day less ultra-violet radiation than a suburban area. During a week of fog very little ultra-violet radiation reached either part of the town. The author notes that the loss of ultra-violet radiation is aggravated in winter owing to the fact that during that season smoke emission by factories covers the whole period of possible sunshine, whereas in summer the hours of smoke emission are only three-fourths of the period between sunrise and sunset.

Dr. Ashworth—not for the first time, as his previous writings show—has made a valuable contribution to our knowledge of the ways of smoke.

MODERN EXTENSIONS OF BEAUMONT'S WORK

The year that has just passed was the centenary of the publication by Dr. William Beaumont of his classical book, *Experiments and Observations on the Gastric Juice and the Physiology of Digestion*. This described his investigations on his patient with gastric fistula—Alexis St. Martin. Beaumont's studies became known throughout the world, and his methods were applied by Claude Bernard to lower animals and later by Pavlov to dogs. Of succeeding physiologists none in America has advanced our knowledge of the subject so much as Professor W. B. Cannon of Harvard, and in a small work compact with information he has brought up to date the modern extensions of Beaumont's studies.¹ The lectures formed a course in the Beaumont Foundation Lectures, and commemorate the hundredth anniversary of the publication of Beaumont's classical work.

Beaumont's book is essentially practical and descriptive of his actual experiments, but at times he was tempted to express certain theoretical opinions regarding the nature of processes which he could not fully determine by observational methods. Among the opinions were those included in a brief chapter entitled, "Of Hunger and Thirst." In regard to both of these sensations Beaumont took a view which was contrary to the accepted physiological teaching of his day, and, though his own explanations were incomplete, he did approach nearer to the truth than the authorities. Beaumont declared that thirst is a sensation arising from the mouth and fauces, a feeling of dryness due to evaporation of moisture from the surfaces of those regions because the passage of the respired air took up the moisture at a rate faster than it could be supplied. He suggested that the failure of a secretion adequate for keeping the surfaces of the pharynx moist was due to a viscid state of the blood resulting from an inadequate water supply. That thirst has a local source in the mouth and pharynx is shown by the relief obtained from painting the back of the mouth with cocaine: sipping a small amount of water will temporarily relieve, or holding in the mouth a substance which causes a secretion of saliva, like lemon, will lessen, thirst. In thirst the salivary glands, whose secretion is about 98 per cent. water, are unfavourably affected by the deficient general water supply. Such a deficiency may occur in people deprived of water, or temporarily when large amounts of fluid are secreted into

the alimentary canal in the form of gastric and pancreatic juice during digestion. Naturally, in our ordinary eating habits we take water with food as we eat. This water is soon absorbed after its passage through the stomach, and serves to compensate for the loss of water from the body in the digestive secretions which are poured out as digestion continues after the meal is over. Instead of there being an increased viscosity of the blood as Beaumont suggested, there is a reduced blood volume and an attendant reduction of the flow of saliva. Beaumont's view of hunger was that it was "produced by a distension of the gastric vessels, or that apparatus, whether vascular or glandular, which secretes the gastric juice." He reasoned that the sensation must have its source in the stomach itself and that it was an expression of local congestion of the mucous membrane, and he cited the fact that application of food to the internal coat of the stomach results in an immediate throwing out of a quantity of fluid which mixes with the food. Careful observation, however, reveals that hunger is intermittent or recurrent in character, and Professor Cannon demonstrated in 1910 that hunger pangs were due to cramp-like tightening of the smooth muscle of the gastric wall. These may occur in the absence of nervous government from the spinal cord and brain, but they are influenced reflexly through the vagi, and may be abolished in strong emotional states. Alcohol and tobacco cause cessation of the hunger contractions, as do vigorous muscular exercise and the old habit of tightening one's belt, at least for a time.

Beaumont noted that in his patient Alexis St. Martin symptoms of general indisposition were associated with considerable disturbance of the processes of the stomach: "no gastric juice can be extracted, not even on the application of alimentary stimulus . . . food taken in this condition of the stomach remains undigested for twenty-four or forty-eight hours, or more, increasing the derangement of the whole alimentary canal, and aggravating the general symptoms of the disease." Not only debilitating disease but also exhausting labour is associated with failure of proper action of the digestive organs. Pavlov's experiments demonstrated the effect of the nervous system on the digestive secretions; not only was there a direct vagal secretory effect on the stomach and pancreas, but a psychic secretion took place when the higher centres of the brain were stimulated by sight or smell of food, and these higher centres then stimulated the vagal nuclei. Cannon showed that attendant on the psychic secretion from the digestive glands there is a psychic increase of muscular tone, both being consequences of vagal excitation. On the vagal and the sacral visceral nerves depend, therefore, important relations of digestion and health. But the digestive process may also be profoundly disturbed through the positive action of the sympathetic division of the autonomic system, a division which is commonly opposed in action to the cranial division and which has, consequently, an inhibitory effect on muscular tone and on the secretions

¹ Some Modern Extensions of Beaumont's Studies on Alexis St. Martin. By W. B. Cannon, M.D. Beaumont Foundation Lectures. Reprinted from the *Journal of the Michigan State Medical Society*, Detroit, March-May, 1933.

of the digestive glands. Beaumont reported the influence of extreme anger upon gastric digestion as observed in Alexis St. Martin. Not only emotion but also pain can affect the digestive process.

Professor Cannon's own work has shown that the inhibition of the digestive process is but a single item in a variegated picture produced by stimulation of the sympathetic nervous system. In addition to the well-known acceleration of the heart and rise of blood pressure, there is a complex of other changes, including redistribution of blood in the body, discharge of extra corpuscles from the spleen, more rapid coagulation of the blood, increase of blood sugar, and dilatation of the bronchioles. All these may be brought about by conditions which excite the sympathetic system; prominent among such conditions are external cold, hypoglycaemia, motion, and emotion. The sympathico-adrenal system is thus a protective agency in times of crisis; but much more an effective factor in maintaining constancy of the internal environment, rendering the higher mammals independent of external changes of temperature and likewise independent of possible disturbances which might be caused by our own actions. This fitness for flight or fight is of great value to the organism. The repercussion of the emotions on digestion suggests some practical advice. Since the total complex of bodily changes associated with emotional excitement is properly interpreted as preparation for struggle, we should try to take a rational attitude towards any exciting incident which may occur. We should decide that if there is action to be engaged in, the excitement should be allowed to run its full course without limitation. If there is nothing to be done in the circumstances, however, it is unwise to permit the organism to be deeply disturbed, and especially the fundamentally important functions of digestion to be inhibited. When an occasion arises which provokes a degree of excitement that cannot be controlled the reasonable behaviour is that of working off in hard physical labour the bodily changes which have occurred in preparation for vigorous effort. We should dig till we gently perspire. Often the excited state can thus be reduced and the body, instead of being upset, is restored to normal.

SILICOSIS

There have been important developments in the past few years in the study of lung disease due to the inhalation of dust. One of their effects has been to make the term "pneumoconiosis" appear almost redundant, since it is now clear that all harmful dusts contain the element silicon in some form, and when fibrosis of the lung follows the long-continued inhalation of dust the condition is, in fact, a silicosis. The hypothesis of mechanical irritation by hard particles of mineral dust has been exploded: the damage to tissue resulting in fibrosis and predisposing markedly to tuberculosis and other infection is known to be due

to the slow solution of silica (silicon dioxide) or other silicon compounds in the tissues. By what precise mechanism the presence of silica favours the progress of tuberculosis is unknown; the evidence that the mineral itself directly stimulates the growth of tubercle bacilli is unconvincing, and it appears more probable that the primary effect is on the tissues, impairing their resistance to infection. It is universally recognized that a large proportion of cases of frank silicosis succumb to tuberculosis; this is indeed implied in the term "miners' plithisis," but there is an uncomfortable suspicion that lesser degrees of exposure to dangerous dusts, insufficient to produce nodular fibrosis in the lung, or indeed any unequivocal signs of silicosis, may predispose to pulmonary tuberculosis. Lanza and Vane¹ furnish statistics which show that the mortality from tuberculosis in a variety of dusty trades is considerably greater than that of the general male population, and that in the male population as a whole, at least in so far as this is represented by a group of industrial policy-holders, the tuberculosis mortality rises steadily to a maximum in middle age, whereas among females it falls to a minimum at this period. These authors compute the number of workers in the United States exposed to a silica dust hazard at over half a million, a figure which may be a salutary shock to those for whom silicosis means only a disease acquired in gold mines and other geographically remote industries. It brings the subject nearer home when we remember that any quarryman or sand-blaster may be exposed to the danger.

Two recent publications threaten seriously to disturb the foundations of our present knowledge of the silicotic process. One is that of Dr. W. R. Jones,² who has revived and confirmed an observation first made by Watkins-Pitchford and Moir in 1916—namely, that the mineral residue obtainable from the silicotic lungs of gold miners includes a large proportion of sericite, or "secondary white mica." This substance, which is present in certain rocks in the form of numerous minute fibres, is a hydrated silicate of aluminium and potassium, and its fibrous structure, totally distinct from that of quartz (silicon dioxide), which has hitherto been regarded as the active element in dangerous dusts, is closely comparable to that of the silicate particles responsible for asbestosis. Jones's evidence that sericite produces silicosis derives not only from its demonstration in the mineral residue of twenty-nine silicotic lungs, but from its distribution in accordance with the frequency of silicosis: thus, in the rock in the Broken Hill Mines, New South Wales, where silicosis is frequent, there is little quartz but much sericite; in the Kolar goldfields, India, where the rock contains a large amount of quartz and sericite is absent, silicosis has hitherto inexplicably been unknown. These propositions have aroused a sharp controversy, and much remains to be done before the specific action of individual mineral constituents can be fully ascertained.

¹ *Amer. Rev. Tuberculosis*, 1934, xxix, 8.
² *Journ. Hyg.*, 1933, xxxiii, 307.

There are more fundamental and revolutionary implications in the experimental results now published by Professor E. H. Kettle.³ It is of interest in the first place that the mineral he used was kaolin, a substance which has not hitherto been classified among the dangerous dusts; chemically it is a silicate of aluminium, and the specimen employed contained numerous sericite fibres. The intratracheal injection of a suspension of this substance, a proceeding which forms a satisfactory and convenient equivalent to prolonged exposure in a dusting chamber, was not found 500 days later to have resulted in the production of nodular fibrosis, the characteristic feature of established silicosis. But when killed tubercle bacilli were added to the kaolin suspension, typical nodules of whorled fibrosis, each with a clump of tubercle bacilli at its centre, were found to have been formed in the short space of 112 days, a result quite unprecedented in any previous experiments with animals, in which it is notoriously difficult, even with long periods of exposure to dust, to induce the formation of true silicotic nodules. What these experiments appear to mean is that infection is an indispensable, or at least probably an almost invariable, factor in the formation of the silicotic nodule: "pure" silicosis, if it exists at all, must be rare, and the disease is properly to be regarded as the product of contemporaneous chemical and infective action. To speak of silicotic "predisposition" to tuberculosis and other infections is probably incorrect, and the distinction drawn in South Africa between "silico-tuberculosis" and "tuberculo-silicosis" may well be without real foundation. The importance of the infective factor is stressed also, though on more trivial immediate grounds, by Policard and Marion,⁴ the subject of whose paper is the lungs of two inhabitants of the Sahara Desert, which, although containing siliceous dust, exhibited no fibrosis, in their view because the infective factor was absent.

Among numerous other recent publications on this subject two more call for mention. Although it is doubtful whether anything justifying the term "acute silicosis" has previously been described, the cases observed by Gardner⁵ appear to merit it. These were fifteen workers who are said to have acquired silicosis after periods of exposure to dust under truly appalling conditions in the boring of a totally unventilated tunnel, and elsewhere, in periods as short as from eight to seventeen months. The lungs contained numerous very minute fibrous nodules, and the existence of coincident tuberculous infection was demonstrable in almost every case. A contribution by Riddell⁶ is notable for his emphatic pronouncement that silicotic tuberculosis is infectious. It has so often been said, particularly in this country, that miners' phthisis is not communicated to other members of the miner's family that Riddell's evidence to the contrary demands serious consideration.

FOOD POISONING

Two American writers, in a report¹ on outbreaks of illness in San Francisco, have expressed the view that the name "food poisoning" should be limited in its definition so as to describe that clinical syndrome resulting directly or indirectly from the ingestion of food contaminated with certain bacteria, and would thus exclude a number of disease conditions which are at present, with the consent of most, included under the title. It is necessary, of course, that there should be names for things. Indeed, *nomina si desunt perit et cognitio rerum*, and in cases in which no name exists it is often a clear advantage to find one. But where a name is already found and approved for use in a particular sense a proposal to alter its application should not, we think, be too hastily acquiesced in. Food, according to the Food and Drugs (Adulteration) Act, includes every article employed for food or drink by man, other than drugs or water, and "food poisoning," as the term is customarily employed, means poisoning by means of food. Such poisoning occurs in the most obvious way when the native food-stuff is itself poisonous or contains a poison. A formidable instance is the mushroom *Amanita phalloides*, which, when ingested, causes fatty degeneration of the viscera and induces symptoms which tend to death in the course of about a week. The leaves of the rhubarb plant, too, owing to the oxalic acid which they contain, are poisonous and have led to fatalities. The young shoots of the potato likewise are dangerous to the unwary, and some species of fish in Japan and the West Indies give rise to pangs at certain seasons. Even honey in the comb may prove a snare, as at Trebizond in 400 B.C., when Xenophon's soldiers, having plundered the local bee-hives, were all found lying about in various stages of illness, and the camp "looked like a battlefield." The description "food poisoning" fits in very well with such occurrences as these. Again, deleterious foreign substances may become artificially incorporated with food, through misadventure or ignorance, in the course of manufacture or preparation. In Lancashire there was a widespread outbreak of poisoning from beer, owing to the presence in it of arsenic as an impurity of the sulphuric acid employed to convert the original starch in the grain to sugar. Another example occurred at Stoke in 1930, when a number of children consumed sweets which had been inadvertently dusted with arsenious oxide. Happily, there was no fatal issue, though the children were sharply sick. In the same year the United States experienced the so-called "ginger paralysis," caused by the introduction of tricesyl phosphate as a flavouring agent into the fluid extract of ginger, at that period, owing to the restrictions on alcohol, a popular beverage. All the above were cases of poisoning by means of food, and so belong, by definition, to the category of food poisonings. Turning now to the forms of illness to which it is proposed that the name "food poisoning" should be restricted, we may note that the symptoms are generally gastro-intestinal in character, and that the infective agent belongs for the most part to the Salmonella group of bacilli. All members of the group, however, are not concerned, and other bacteria are implicated.

⁶ Amer. Rev. Tuberculosis, 1934, xxix, 36.

¹ C. G. J. C., and Gray, J. P.: Journ. Amer. Med. Assoc., 1933, ci, 973.

Staphylococci have been incriminated in the United States. The source of the infection in the food may be a rodent or a sick meat animal, and milk has been known to convey *B. aertrycke* and *B. enteritidis* from the cow to man just as it carries *B. tuberculosis* and the Brucella of undulant fever. The process, therefore, is of an infective character, implying bacterial invasion of the tissues, though from this generalization botulism would require to be excluded and also certain cases due to the Salmonella group. Under the existing nomenclature the name "food poisoning," in its original sense most aptly applied to such attacks as those produced by Amanita and arsenic, has been enlarged, not inaptly, to include cases of the infective group under the title "bacterial food poisoning." The terminology, if not ideal, is at least convenient and sanctioned by usage. If, however, any rearrangement is thought necessary there would be no good case for withdrawing the description "food poisoning" from its original and obvious uses: rather, the infective cases should be excluded and a new name found for them. Not, indeed, that this is suggested. We are averse to removing a landmark without good cause. What is perhaps more important is that the term "ptomaine poisoning" should cease to be applied to cases of illness ascribed to food. Ptomaines are not poisonous when taken by the mouth, and in any event only make their appearance in foods so transformed by putrefaction as to warn off any intending consumer.

SCHOOLS TO-DAY

The National Union of Teachers has accomplished an effective presentation of history and a fine piece of propaganda in its new publication, *The Schools at Work*.¹ It is mainly a pictorial record or survey of what is now being done in schools which are maintained or aided by public funds. The illustrations are abundant and varied in character, well chosen, and excellent in themselves. They depict the activities of all classes of such schools—elementary, secondary, technical, central and special, urban and rural—and, in addition, show some characteristic features of what ought to be regarded as parts of the health, rather than of the education, services—nursery schools, and medical inspection and treatment of school children. There is useful letterpress among the many pictures, and short articles by three who have held the office of President of the Board of Education (Lord Halifax, Mr. H. A. L. Fisher, and Lord Eustace Percy), by Sir Henry Richards, late Senior Chief Inspector of the Board, by Dr. Cyril Norwood, and by Sir Frederick Menzies. Nothing could better exemplify the wisdom of the method chosen by the compilers of this publication and the efficiency with which it has been carried through than the contrast between the relatively commonplace content of these articles (though Lord Eustace Percy's thought on technical schools is worth developing), and the vivid and stimulating impression produced by the fifty pages devoted to the pictorial record. This striking effect is heightened by the inclusion of some views of schools or classes as they were fifty, forty, or thirty years ago. It is not without considerable emotion that the worker in the educational field in

the early years of the present century, like the writer of this note, in looking at these pictures will recall the struggle to get a piano, a sewing-machine, or a lath introduced into the elementary school, and the opposition these things encountered, even in some of the most progressive of education authorities. It must surely be a matter for general rejoicing to be enabled to realize so keenly the contrast between the interest taken by the public in the children of to-day and the varied and personal care devoted to them; and the hostility or grudging acquiescence which formerly characterized a large section of public opinion. There could scarcely be a better corrective than this publication to the lack of intimate knowledge and the sometimes ill-founded criticism of our educational system still too common among some members of the professional and upper classes of the community.

DINITROPHENOL

In an annotation on dinitrophenol for reducing weight, in the *Journal* of March 24th (p. 539), mention was made of the recent death of a young professional dancer from poisoning by an overdose of a nitrophenol compound. This matter was raised at the last meeting of the council of the Pharmaceutical Society, held on April 4th. It was reported that a letter had been received from the Home Office indicating that the Home Secretary would like to know whether the council, pending enforcement of the Pharmacy and Poisons Act of 1933, was prepared to initiate the steps necessary to add to Part I of the existing Poisons Schedule such nitrophenols and preparations containing them as were, in its opinion, likely to be retailed to the public. The council had before it also a memorandum from Professor E. C. Dodds on the therapeutic action and toxicity of these drugs. The council adopted a formal resolution, and directed it to be sent to the Privy Council for consideration and approval, declaring that the Schedule to the Poisons and Pharmacy Act, 1908, ought to be amended by the addition to Part I of the following words: "dinitrophenols, dinitrocresols, preparations or admixtures containing dinitrophenols, preparations or admixtures containing dinitrocresols."

ROYAL STATISTICAL SOCIETY CENTENARY

Next week the Royal Statistical Society celebrates its centenary. The Prince of Wales, honorary president, will take the chair at the centenary meeting on Tuesday, April 17th, and in the evening a distinguished company of guests from all parts of the world will be present at the centenary banquet. Statistics and statistical methods are of importance in so many fields of life that the society's presidents and officers have included men eminent in many subjects. Statesmen and civil servants have predominated, but members of our profession have been by no means backward. The following medical men have occupied the presidential chair: William Farr (1871-3); William Augustus Guy (1873-5), an enthusiastic statistician and generous benefactor of the society; T. Graham Balfour (1888-90); Frederic J. Mowat (1890-2). Of the present council of the society, three—Professor Major Greenwood (honorary secretary and vice-president), Sir William Hamer, and Sir Arthur Newsholme—are members of the profession.

A TUBERCULOSIS SETTLEMENT

Dr. J. B. McDougall, medical director of the British Legion Village at Preston Hall, near Maidstone, has drawn up a report on the work there during the year ending September 30th, 1933, which is of exceptional interest and value in connexion with the administrative and preventive sides of the campaign against tuberculosis. The British Legion took charge of this institution in 1925, and the report gives a summary of the progress made since then, with special reference to the practical working out of the modern conception that successful treatment of tuberculosis implies adoption by the patients of a health-preserving mode of life. It has been estimated that of 100 tuberculous patients fifteen remain medical problems, needing for the remainder of their days some appreciable degree of rest; about fifty return to their previous employment or some modified branch of it; and about thirty-five middle-stage cases remain medical and economic national responsibilities, a completely new mode of life being necessary for them if the beneficial results of their initial treatment are to be conserved. Sanatorium treatment gives too often very disappointing results owing to lack of adequate after-care, and the claim is made for the village settlement scheme that it forms the only satisfactory method of prolonging life, preventing relapses, promoting complete arrest of the tuberculous process, detecting deviations from the normal in each individual patient, supervising the family life, providing occupation on a wage basis, and assuring the economic position of the patient and his children. Dr. McDougall brings forward a great deal of evidence in support of this contention. Preston Hall is conducted generally on the lines found so successful at Papworth. The records of the last five years show that at any given time there are approximately one-third advanced cases, one-third chronic ambulatory cases, and one-third first and second stage cases undergoing treatment. Preston Hall is limited to ex-Service men and their dependants, but the demand for beds exceeds the supply, especially during the summer months. It is now recognized that a large proportion of the patients need a residential period in the Settlement of at least five years. After such a period experience shows that the settlers should be able to take their places once again in the normal life of the community. The concurrent medical supervision of the families has resulted at Preston Hall in the appearance of a juvenile population of 285 without a single case of tuberculous infection. The Settlement comprises the sanatorium, accommodating 280, for the treatment of all cases admitted; workshops in which patients and settlers can find congenial employment suited to their physical resources; and the estate, accommodating unmarried patients in hostels and the married in houses. Occupational therapy, graduated for individual requirements, leads the patient from the sanatorium to the village settlement proper, and thence back to the outside world again. Dr. McDougall believes that it is better as a general rule to have several different industrial departments, each with a turnover of £5,000 to £10,000 annually, than to have one large department with a staple industry. The industries at Preston Hall include the manufacture of portable buildings, printing, the supply of suit cases,

attaché cases, and other articles in fibre or leather for the travelling public, graining wood and marble, the running of the village stores, soap stamping, and various kinds of work associated with the management of the estate, accountancy, and gardening. In September last there were 168 patients employed in the Settlement, of whom 140 were married. Every tenant pays rent, the minimum being 3s. 9d. a week and the maximum 16s. 3d., these rents including the local rates. The report includes suggestions for the expansion of village settlement work in Great Britain, and a recognition of the difficulties that have to be faced. Dr. McDougall considers that local authorities are at a distinct disadvantage in embarking upon settlement work. Few of the industrial ventures pay their way at the beginning, and capital has to be sunk.

COMMITTEE FOR RESEARCH IN MENTAL DISORDERS

The Medical Research Council, in consultation with the Board of Control, has appointed a new committee to advise and assist it in the promotion of research into mental disorders. The reconstituted committee will include representatives not only of psychiatry, medical psychology, and the study of mental deficiency, but also of neurology, physiology, biochemistry, pathology, and genetics.

The chairman of the committee will be Professor E. D. Adrian, M.D., F.R.C.P., F.R.S., a member of the Medical Research Council, and the following will also serve: Sir C. Hubert Bond, K.B.E., D.Sc., M.D., F.R.C.P., Board of Control; Bernard Hart, M.D., F.R.C.P., University College Hospital, London; Professor D. K. Henderson, M.D., Royal Edinburgh Hospital for Mental and Nervous Disorders; T. A. Ross, M.D., F.R.C.P., Cassel Hospital, Penhurst; E. O. Lewis, D.Sc., M.R.C.S., Board of Control; C. P. Symonds, M.D., F.R.C.P., Guy's Hospital, London; J. H. Quastel, D.Sc., Cardiff City Mental Hospital; J. G. Greenfield, M.D., F.R.C.P., National Hospital for Nervous Diseases, London; F. L. Golla, M.B., F.R.C.P., Maudsley Hospital, London; and L. S. Penrose, M.D., Royal Eastern Counties' Institution, Colchester. Sir David Munro, K.C.B., M.B., of the Council's staff, will act as secretary of the committee.

THE LATE PROFESSOR A. B. MACALLUM

News has been received of the death of Dr. Archibald Byron Macallum, F.R.S., the eminent Canadian physiologist, who retired from the chair of biochemistry at McGill University, Montreal, in 1929, and was then appointed emeritus professor. He had formerly been professor of physiology and physiological chemistry in the University of Toronto, president of the Royal Society of Canada, and administrative chairman of the Canadian Advisory Council for Scientific and Industrial Research at Ottawa. Professor Macallum was vice-president of the Section of Anatomy and Physiology when the British Medical Association met at Montreal in 1897, and of the Section of Physiology at the Toronto Meeting in 1906.

Sir Henry Dale, M.D., F.R.S., will deliver the Linacre Lecture in the department of physiology of the University of Cambridge on Saturday, May 5th, at 5 p.m. His subject is "Chemical Transmission of the Effects of Nerve Impulses."

Nova et Vetera

THOMAS SHORT, M.D.: AN EIGHTEENTH CENTURY PRACTITIONER IN SHEFFIELD

Thomas Short was a Scotsman who commenced to practise in Sheffield about 1728. He had become acquainted with Sir Hans Sloane before that date, and from the correspondence preserved in the Sloane collection it appears that he wrote to Sloane in reference to some of his wealthier patients. Possibly Sloane's influence was helpful to him, and he certainly obtained a very good practice. A curious testimonial to his success as a physician is given in the *Gentleman's Magazine*:

"The first Marchioness of Rockingham in a mischievous conversation at table, happening to say 'that she would trust her life in the hands of Dr. Short in preference to any one of the faculty,' Mr. Staniland, a clergyman from Worsbrough, bluntly replied, 'I do not like him at all.' 'Why so?' 'Because,' answered Staniland, 'had it not been for the doctor I should have been rid of my wife several years ago.'"

All the local historians in describing Short agree in calling him eccentric; they mention not only that he retained his Scottish accent, but also, what is much more unusual, they allege that he stuck to the diet of his native land, and he is even credited with giving porridge parties to his friends. Another piece of information regarding him is that he always slept over a coal-house to preserve his lungs.

Short's chief activity apart from his practice was the production of a large number of books on medical and allied subjects. Unfortunately his writings are more numerous than valuable, and this judgement was passed as near his own time as 1807. He published five or six books on mineral waters; two books on epidemiology; various discourses on tea, milk, and wines; on medicinal plants; and his last work, *The Increase and Decrease of Mankind*, appears to be an incursion into vital statistics.

Two of the books on mineral waters (1734 and 1740) were intended to form a complete survey of the spas of England. In collecting the material for these books Short visited as many places as he could, taking with him various instruments and bringing away samples of the waters for examination at home. The demands of his practice, however, forced him to ask the help of friends in obtaining specimens. Richardson, a botanist of Bradford, was one to whom he appealed, and in writing to give instructions as to the transport of the samples, Short adds, "we have such a crowd of new physicians coming or come to this country that I dare not at present take my pleasure rides." He devotes many pages to the experiments he performed with these samples. Apparently the kitchen was his laboratory, and he surrounded the fireplace with cups or saucers full of mixtures of mineral waters with all sorts of things, including blood, serum, and bile. The results in some cases are measured by the sense of smell alone, and vary from "began fetid" to "past enduring in the house." Perhaps these accounted for his choice of a sleeping place. In later works he writes largely of a water from Holt Neville in Leicestershire. This he rented from the landlord, and he sent some of his patients from Sheffield there. Stukeley records that some of this water was sent to the Royal Society in 1748.

In finding the positions of springs Short made use of several books of reference, such as *Magna Britannia* and the "histories" of several counties. On two occasions he mentions inaccuracies in these sources of information. Speaking of Tibshelf he says it has a reputed purgative mineral water.

"but how the authors of the *Magna Britannia* have removed it to Stanley is hard to tell. For I could only meet with a large horse pond of common water; nor did the inhabitants ever hear of a spaw there, before the kind gentlemen presented them with an invisible one."

After describing some springs in Staffordshire he goes on:

"From Dr. Plat's long detail of sulphur waters in his history of Staffordshire, we expected to find a great many

others in this country. But to our great surprise they were all gone when we went carefully to each place in question, so that we must conclude, either that they were never there or the sulphur was all exhaled with the fume of his wine, or he buried them where the duck laid several eggs in a day or at Newport ominous bridge. The like dance, with near the same success, he led us in Oxfordshire. No Englishman ever had a capacity more equal to the work he undertook, and none could discharge it with less regard to the truth and their own reputation."

It is an extraordinary fact that the only writer of modern times who has tried to make use of Short's works makes similar complaints. The remarks of Dr. Charles Creighton on the two books on epidemiology are worth quoting for that reason.

"A *General Chronological History of the Air, Weather, Seasons* is the only book of the kind in English previous to my own. It is everywhere uncritical and credulous, and often grossly inaccurate in dates. His other work *New Observations on City, Town and County Bills of Mortality* shows the author to much greater advantage."

Speaking of the second book, Creighton says:

"Dr. Thomas Short, a man of great industry, about the middle of last century obtained access to a large number of parish registers, and worked an infinite number of arithmetical exercises upon their figures. His abstract results or conclusions are colourless and unimpressive, as statistical results are apt to be for the average concrete mind; nor can they be made to illustrate the epidemic history of England with the help of his companion volumes, *A General Chronological History*, for these extraordinary annals are for the most part loosely compiled from foreign sources, bringing into one focus that most scattered reference to disease in any part of Europe, and that too without criticism of authorities, but often with surprising credulity and inaccuracy. That so much statistical or arithmetical zeal and exhaustiveness (in the work of 1750) should go with so fatal a deficiency of the critical and historical sense (in the work of 1749) is noteworthy and perhaps not unparalleled in modern times."

Dr. Creighton made a close study of these volumes, but on each occasion when quoting them refers to "the laborious Dr. Short" or "Short, a professed epidemiologist." Short is supposed to have spent eighteen years on these two books.

Short and Dr. John Rutty of Dublin appear to have worked along similar lines. They both made observations on the weather; they took an interest in epidemic diseases, and frequently corresponded on the subject. Both made experiments to find a solvent for the stone, but these investigations no doubt were stimulated by the large reward paid by Parliament to Mrs. Joanna Stephens. Rutty's work on the *Mineral Waters of Ireland* is dedicated to Short, among others. None of Short's books gives any details of individual cases. "A loathsome miserable carrion" is as far as he gets in his books on water. He did, however, publish three cases in the *Edinburgh Medical Essays*, but the descriptions he gives are very poor. We cannot, therefore, obtain any idea of his attainments in clinical medicine.

In his later years the competition of other practitioners increased, and in 1762 he retired to Rotherham, a circumstance which has led to some confusion as to his real domicile. He died in 1772 in his eightieth year, we are told, in rather poor circumstances.

CHARLES L. SUTHERLAND.

Mohammed Shalin Pacha (*Bull. Off. Internat. d'Hyg. Publique*, January, 1934) states that typhus has been endemic in Egypt since 1911, reaching its height in 1916, when there were 30,507 cases. After the war there was a decline in its incidence until 1931, when only 265 cases were notified. In 1932, however, owing to the financial crisis with subsequent malnutrition of the poorer classes, lack of hygiene, and individual cleanliness, the disease assumed epidemic form, there being 2,298 cases in 1932, with a fatality rate of 17 per cent., and 6,621 cases from January 1st to July 24th, 1933, with a fatality rate of 12 per cent. The general condition was better, and severe nervous symptoms and the appearance of an eruption were rare, so that the infection resembled Brill's disease. Prophylaxis consisted in isolation, de-lousing of the patients, and disinfection of the clothes by steam.

SOCIETY FOR THE STUDY OF INEBRIETY

JUBILEE CELEBRATION

The Society for the Study of Inebriety celebrated its jubilee on April 10th, when Sir Humphry Rolleston, the president, delivered a commemorative oration on the aims and work of the society. The oration was preceded by a luncheon, at which Sir Hilton Young, Minister of Health, was the principal guest. Owing to parliamentary exigencies, however, the Minister had to leave without making a speech.

Sir Humphry Rolleston gracefully alluded to the principal guests present: the Bishop of Norwich, Lord D'Abernon, Sir Thomas Barlow ("the doyen of the profession and of our affections"), Sir Josiah Stamp, Sir William Willcox, Sir Holburt Waring, P.R.C.S., Mr. Warren Low, President of the Royal Society of Medicine, the Master of St. John's College, Cambridge, and two of the daughters of the founder of the society (Dr. Norman Kerr). He coupled the toast of "The Society" with the name of Dr. Harry Campbell.

Dr. Harry Campbell, in a brief reply, said that it might be asked, after fifty years, whether the question of addiction had not been completely thrashed out, but the fact was that new problems of addiction were constantly arising. One of the most recent forms was addiction to drugs for the purpose of slimming the figure—a habit which had led to quite serious illness, and even to suicide. One of the most remarkable forms of addiction of which he had had experience was to methylated spirit; in the old days it was reported that the anatomical attendant at his hospital was in the habit of drinking the methylated spirit which should have been used for the preservation of specimens. As for the treatment of drug addiction, it could not be said that much advance had been made. No medicament had been discovered as sure in its action in addiction as insulin in diabetes. In fact, addiction was altogether too severe a malady to be cured by mere drugs. What must be done was to endeavour to overcome the craving, and build up the patient in health and sanity. He added that as the years had passed he had become more and more convinced of the good which the society was doing, and he ended with a tribute to Dr. T. N. Kelynack, its honorary secretary for thirty-two years.

The Society in Retrospect

After the luncheon party the annual general meeting took place in the rooms of the Medical Society of London, when Sir Humphry Rolleston delivered from the chair a commemorative oration on the aims and work of the society during its fifty years' existence. He said that in the organization of the society, which started with a membership of 165, the guiding spirit was Norman Kerr, and the present year was not only the jubilee year of the society, but the centenary of its founder's birth. Norman Kerr was a Glaswegian who was at first a journalist, and afterwards entered the medical profession, graduating M.D., C.M. at Glasgow in 1861. During the whole of his career he carried on a vigorous campaign for total abstinence, at a time when the subject was looked upon as freakish, when real sacrifice was demanded of its apostles, and when the medical profession regarded alcohol with an indulgent eye. Norman Kerr was an energetic officer of the United Kingdom Alliance, an active member of the Church of England Temperance Society, and honorary secretary for more than ten years of the Homes for Inebriates Association, the body responsible for the Rickmansworth Home, which was the first institution of the kind in this country, and, Sir Humphry Rolleston added, had thoroughly justified the foresight of its founders. Norman Kerr was also chairman of the British Medical Association committee on legislation concerning inebriates, which reported in 1891.

But the foundation of the Society for the Study of Inebriety and his presidency of it for fifteen years, until his death in 1899, was Norman Kerr's outstanding achievement. At the inaugural meeting he himself clearly

defined inebriety as "a diseased state of the brain and nerve centres, characterized by an irresistible impulse to indulge in intoxicating liquors or other narcotics, for the relief these afford, at any peril." He regarded inebriety as essentially a disease allied to insanity, and insisted that it should be treated medically, and not as if it were a crime. His whole-hearted devotion to these principles was largely responsible for the amendment of the Habitual Drunkards Act of 1888 and the Inebriates Act of ten years later. He forged many links with American and Continental authorities on the subject, and in the year of Queen Victoria's jubilee he organized a colonial and international congress on inebriety, which ended with a banquet with non-intoxicating wines and twenty-five speeches!

Turning from the founder to the society itself, Sir Humphry Rolleston mentioned other presidents: among those who have passed away, William Wynn Westcott, Mary Scharlieb, T. Clave Shaw, T. B. Hyslop, and Sir Alfred Pearce Gould; and among those who remain, Dr. Harry Campbell, Lady Barrett, Mr. McAdam Eccles, Mr. C. J. Bond, Sir William Collins, Sir William Willcox, and Sir Arthur Newsholme. Still on the personal side, the orator mentioned how fortunate the society had been in having had the services, since 1902, of Dr. T. N. Kelynack as honorary secretary. During its half-century of activity the society, which was controlled by its medical members, well supported by their lay associates, had aimed at a scientific study of alcoholism and drug addiction. It had no declared policy of total abstinence, though some of its individual members might have strong convictions on the subject. The great change in the general attitude towards temperance, which had marked the last fifty years, as also the change in professional opinion with regard to the therapeutic use of alcohol, owed not a little to the work of the society and to the influence of some of those just named, as well as of other noteworthy supporters, such as Sir Benjamin Ward Richardson, Sir Victor Horsley, Sir G. Sims Woodhead, and Sir Thomas Barlow. From its start the society brought out records of its meetings in pamphlet form, and in 1903 the *British Journal of Inebriety* was begun, since when it had been published quarterly.

Sir Humphry Rolleston then passed in brief review some of the subjects of the discussions. At the first ordinary meeting the aetiology of inebriety was introduced by that famous naturalist W. B. Carpenter. An early paper of interest was on ether drinking in Ireland, by Ernest Hart, then Editor of the *British Medical Journal*. The interlocked influences of heredity and alcohol had been discussed, and after a paper on that subject in 1899 a committee was appointed to investigate the conditions under which the tendency to inebriety was capable of transmission to offspring; the result was a great difference of opinion, only nine members out of fourteen signing the report, and five of those nine appending some reservation. The problems of alcohol, eugenics and race degeneration, female inebriety, and the relation between alcohol and prostitution had all provided matter for valuable papers. The bearing of the subject on disorders of the nervous system and on venereal disease had been studied; the treatment of alcoholism had been many times explored; and the thorny subject of the use of alcohol in medicine had not been shirked. Medico-legal aspects had been given their proper importance, and the still burning question of alcoholic indulgence in relation to motoring was the subject of a paper in 1925. Much useful information could also be gleaned from the society's transactions on the subject of drug addictions other than alcohol. Finally, tobacco made an early appearance in the discussions in 1885, in an address by Lennox Browne on the influence of alcohol and tobacco on the voice. The late Professor W. E. Dixon, in his Norman Kerr Memorial Lecture in 1927, deprecated the view that tobacco was a serious form of addiction, and gave a list of drugs in which heroin took the first place in seriousness, followed in order of importance by cocaine, morphine, Indian hemp, opium, alcohol, and tobacco; but a severe indictment of the cigarette habit was made by Dr. J. D. Rolleston before the society

last year. A healthy freedom of opinion has always characterized the society's proceedings.

A vote of thanks was accorded to Sir Humphry Rolleston on the motion of Sir Thomas Barlow, and the remainder of the proceedings was the formal business of an annual meeting.

FUTURE OF NURSING HOMES AND HOSPITAL PRIVATE WARDS

At a meeting of the West London Medico-Chirurgical Society on April 6th, with Mr. H. TYRRELL GRAY in the chair, a discussion took place on the future of nursing homes and private wards in hospitals.

Mr. B. SANGSTER SIMMONDS spoke of the revolution which had taken place since the beginning of the century in provision for sickness. At one time it was customary to be born at home, to pass through any infectious fever at home, to have even a major operation performed at home, and, finally, to die there. Now even minor ailments were treated in institutions, and it was rare for operations to be undertaken in a private house. Nursing homes thirty years ago were converted private dwellings, and for accommodation heavy fees were charged. To-day much attention was paid to construction and special equipment. The recently built London Clinic and Nursing Home, in Devonshire Place, had 200 beds, and it was contemplated to build another in the West End with 600 beds. Along with this had come the "pay-beds" in hospitals, so that the smaller and inferior nursing homes were beginning to feel the pinch. But the problem of accommodating middle-class patients was increased rather than diminished. The rich were able to command luxury homes and the poor had the public provision, but the difficulty was to find accommodation for people of moderate means. Was it possible for private enterprise to provide an adequate amount of nursing home accommodation on a remunerative basis with a scale of charges in the neighbourhood of seven guineas a week inclusive of everything except medical and surgical fees? A scheme had recently been suggested for providing 600 beds at seven guineas a week per bed, but this was only possible if the relatively low charge attracted a certain number of the more chronic and lighter cases, requiring little in the way of nursing and expensive dressings and drugs; or people who would go into a nursing home for a period of observation or special diet or rest. Nursing alone cost an average of £2 per week per bed. The economic unit for the nursing home had still to be decided. One of 50 beds was too small, one of 600 beds was probably too large. When the economic size had been found by experiment it was possible that a charge of seven guineas a week would produce a remunerative result in Central London, and in outlying districts the charge might be even less. To raise the necessary capital to build nursing homes of such a standard and size would be difficult; perhaps it would be more feasible to have a central institution in the West End, with subsidiary institutions in the suburbs, or even in the provinces. Now that so much of the treatment of the sick poor had been taken over by the authorities there was no doubt that the voluntary hospitals could provide accommodation equal to that of the best nursing homes on a profitable basis at about seven guineas a week, but there was the great objection that the voluntary hospitals would never receive the support of the whole medical profession so long as they managed their beds on the present system whereby the patient was removed from his regular doctor and placed under the care of a member of the staff. Could hospitals build nursing homes out of funds subscribed for that purpose, and allow general practitioners (or consultants) to send in their patients under their own care, such cases to have the laboratory and other assistance of the hospital (which would, of course, be paid for), and the consultants and specialists attached to the hospital to be available? If this plan were adopted the varying needs of London might be met by the establishment of

one or more large institutions in the West End and the extension of pay-beds in connexion with London hospitals.

Dr. E. A. GREGG said that the average general practitioner was in a position of complete bewilderment. His activities were being steadily circumscribed, and not the least of the "encroachments" were the activities of the hospital. Any movement for an extension of such activities, therefore, must be suspect. It was not to the advantage of the community to diminish the field of the general practitioner. In the nursing home the practitioner could follow his patient and remain the doctor in charge, the consultant coming in in the capacity of consultant only. But in hospital paying wards the practitioner was not as a rule welcome. One great obstacle which the medical profession had to overcome was the engrained idea that people were entitled to their "doctoring" without charge. They were ready to pay for articles of luxury, for motor cars and wireless, but their medical care in sickness must be obtained at a cheap rate or for nothing at all.

Mr. W. McADAM ECCLES said that there were about 1,300 pay-beds in connexion with the 140 voluntary hospitals in the area of King Edward's Hospital Fund for London. The number was totally inadequate for the persons of the intermediate class, the class between the poor, for whom there was public provision, and the well-to-do, who could afford the best nursing home accommodation. The number should be multiplied at least by three. The disadvantage of voluntary hospital provision for these cases was that, when the hospital had a closed staff, the general practitioner could not follow his patient into the paying ward. One of the fundamental principles in the British Medical Association's proposal for a general medical service for the nation was the "Every effort should be made to provide medical and nursing service facilities in institutions (home hospitals) where the family doctor may treat those of his own patients who need such provision and who could thus remain under his care." At the same time, it would be regrettable if paying wards attached to voluntary hospital disappeared, for they served a useful purpose, and, so far as the smaller hospitals were concerned, it was not quite true that the general practitioner had no opportunity of coming in and, partially at any rate, treating his patient. But there was a need outside the centre of London for institutions which the practitioner could look upon as the "home hospital" for the locality. With regard to the financial provision, he had had the honour of being a good deal concerned in the working out of the plan for the British Provident Association, which suggested, some years ago, a method of obtaining the capital necessary by means of a Founders' scheme. Mr. Eccles took as an example such a typical middle-class district as Ealing, on the periphery of London, and suggested the size and cost of a home hospital to serve the population. The basis of computation was that two persons out of every hundred during the year would need, and ought to have, institutional treatment under their general practitioner. The capital cost per bed, including the help of physician or surgeon and all ancillary services, the due apportionment for administrative and nurses' accommodation, together with, what was very important, a sinking fund charge, was something like £1,000. It was somewhat difficult to run a "home hospital" at a moderate charge to patients and cover all cost. It could not be done, so far as one could see at the present time, under six guineas. This, however, was not an unduly large sum for a person of this class faced with the emergency of serious illness, provided that he had in some way insured against such emergency up to a certain limit. Even if the grant in aid was only up to £5 a week, and the nursing home charges were six or even eight guineas, the extra should not be beyond the compass of the persons for whom this provision was intended. Mr. Eccles spoke with some impatience of those who, while ready to spend freely on non-necessities, grudged any provision for serious illness. That very day a man had confessed to him that he spent seven shillings a week on cigarettes, and yet could not afford a guinea or so a year subscription to the British Provident Association! That association, by the way, also provided for the cost

of certain services, consultations, operation fees, and the necessary attendance of the consulting physician. It was of some importance, if only for the psychological encouragement of the patient, that the consulting physician should see the patient more than once in any really serious illness; while the surgeon, of course, was compelled by the nature of the case to see the patient more frequently. Mr. McAdam Eccles thought that such a development as he had indicated was long overdue, but he had to remark that the real stumbling-block was the medical profession itself in quite a number of areas.

Dr. F. J. McCANN said that twenty-five years ago he endeavoured to induce the Samaritan Hospital to acquire premises next door and start an independent hospital where general practitioners could be admitted to treat their patients; but the idea was then too far in advance of the times, and one of the chief objections came, not from the medical but from the nursing staff, the matron of that day declaring that there would be too many people "interfering." That idea still existed in nursing homes, where the general practitioner was not always very warmly welcomed. What was required, in his view, was a separate institution in connexion with hospitals, running entirely on its own, for the reception of paying patients, but with access to the ancillary services provided by the hospital.

Dr. G. C. ANDERSON said that there were three main reasons for the demand for pay-beds: the progress of scientific medicine, the domestic difficulties of middle-class households, and the inability of some sections of the community to provide medical attendance of a specialist nature from their own unaided resources. He looked forward to the extension of the contributory scheme movement to the middle classes. But if pay-beds were to be provided through some system of insurance a scheme must be developed for giving all sections of the profession the same opportunity of participating in the arrangements. Every practitioner did not want to be an operating surgeon, but he did want to be able to follow his patient into an institution and treat him as he would have done in private, calling in a consultant if the needs of the case demanded it. As for the development of the "pay-bed" system, he believed in the principle of separate blocks attached to the hospital. It must be remembered that the doors of the municipal hospitals were open to every member of the community, and unless the voluntary hospitals did develop this pay-bed provision in separate blocks or institutions the municipal hospitals would take their place.

Dr. H. H. SANGUINETTI mentioned that at the London Temperance Hospital the general practitioner was allowed to come in. It seemed to him that if this plan could be worked in the ordinary nursing home it could be worked in the general hospital. Mr. DUNCAN FITZ-WILLIAMS spoke of the rivalry between voluntary and municipal hospitals, in which, in his view, on account of the large resources of municipal provision, the voluntary hospitals were bound to be worsened. At his own voluntary hospital the state of funds was such that the staff hesitated to make any requests for desirable provision, whereas the L.C.C. would accede, say, to the appointment of a couple of new assistants in the pathological department "without looking over its shoulder." Mr. HOWARD STRATFORD urged that the public be educated to regard charges for illness as a capital expenditure, instead of, as now, trying to meet them out of income.

A layman, Mr. N. G. LOUGHNANE, pleaded the case of the man with £500 a year, nearly half of which went on income tax, rent, rates, insurances, and the education of his children. Such a man very often had no capital, or when he had it was jealously guarded, and if there was a doubt in the case he would prefer to wait for his operation, and in the end consider it a duty to his family to have it in the public wards of the general hospital. The weekly charge at the nursing home was not the deterrent, but the additional fee of the operating surgeon. If instead of seven guineas a week for accommodation a man were called upon to pay ten guineas a week, including every fee for every doctor, he would be much

more amenable. A hospital of fifty beds, always full—that was merely a matter of rationalization—would yield an income of £26,000 a year, out of which £3,000 could be afforded for the consulting surgeons, £3,000 for the nurses, and £500 or £1,000 for rent charges. He saw no reason why a small hospital like that should not be as self-supporting as a hotel, and it was no more expensive to run, for although it had a nursing staff it had not the "side-shows" which were necessary to hotel administration.

Dr. G. SLOT, who had visited nursing homes and clinics in France, Germany, and Holland, said that these compared favourably with the average nursing homes in London, which were miserably furnished, badly equipped, and expensive. Many of the Continental clinics were household words in their locality, and sought after by rich and poor on the same principle as the Mayo Clinic in America, where the standard charge was 10 per cent. on income. Dr. VAUGHAN PENDRED spoke with approval of a recent leading article in the *British Medical Journal* in which the causes of the diminution of the demand for the general practitioner's services had been analysed, depressingly, but truthfully. Mr. TYRRELL GRAY thought that their lay visitor, in complaining of the amount of the surgeon's or specialist's fees, had overlooked the large expenditure of capital on education and equipment to which these members of the profession had been put.

Mr. SANGSTER SIMMONDS, winding up the debate, said there appeared to be general agreement that in nursing homes or private wards, where the patient contributed the whole cost, the general practitioner should remain in charge of the patient, calling in the consultant if necessary. He agreed with Dr. Anderson that the homes for paying patients should be entirely separate institutions from the hospitals, but the ancillary services of the hospitals should be open to them. No private institution, limited to one building, could bring down the charge to lower than seven guineas, but an institution in association with a voluntary hospital might bring it to six guineas, and without recourse to charity. An inclusive fee of ten guineas would "drive the consultants and specialists to the workhouse."

England and Wales

Milk for School Children

Commenting on the Government proposal to distribute a daily ration of milk to children in the elementary (and perhaps other) schools, a recent letter from Miss Olga Nethersole, honorary organizer and founder of the People's League of Health, states that the science, medical, and veterinary councils of the League desire to emphasize the urgent necessity of steps which will ensure that the milk will not be a medium for the conveyance of tuberculosis and other milk-borne diseases. A memorandum on the subject, prepared by a special committee of the League, is now available, and it is urged that the recommendations contained in it should be put into operation. The memorandum pays tribute to the nutritive value of milk for growing children, and outlines the dangers which it may offer in transmitting infection. It states that at least 40 per cent. of the cows in this country are infected with tuberculosis, and at least one in every 100 cows is actively discharging tubercle bacilli into the milk or elsewhere. It is suggested that 500 fresh cases of undulant fever occur each year in England and Wales, and at least twenty to thirty out of every 100 samples of raw milk can be shown to contain the causative organism. Precautions advocated to secure safe milk are as follows. (1) Pasteurized milk is recommended, and should be labelled "Grade A Pasteurized" or "Pasteurized." (2) Ordinary milk should not be given raw to children, but should be rendered safe by boiling. (3) If raw milk is to be used it should be labelled either

"Certified" or "Grade A (T.T.)." (4) Grade A milk is milk produced under cleanly conditions, though not from tuberculin-tested cows, and cannot be recommended in the raw state. It is pointed out that the guarantee of clean milk from pasteurization is only obtained when the milk is pasteurized under conditions laid down by the Ministry of Health, with the proper supervision which this implies, and is sold under licence as "pasteurized milk."

The General Infirmary at Leeds

In connexion with the great appeal that is being made for the large sum of £250,000 to carry out the extensions of the General Infirmary at Leeds which have been outlined in these columns, the table of statistics which will be presented at the annual meeting may prove of interest. The figures show that the hospital is working at very high pressure. The total number of beds and cots at the Infirmary and at the two semi-convalescent hospitals, known as the "Ida" and "Robert Arthington" hospitals, is given as 628. This figure is, however, based on the assumption that all the emergency beds, such as those for special cases in the sitting rooms attached to the large wards and those used for isolation purposes, are in commission. The average daily number of these beds occupied last year was 559, leaving a margin which is by no means a large one in these days of emergencies and motor accidents. The smallest number of patients in the two institutions on any one day was 456, and on one day the total reached 626, which, in respect of what has been said above as to the distribution of the beds, meant serious overcrowding in some of the wards. The total number of patients admitted during the year 1933 was 13,654, of whom 2,425 were children. Receiving attention in the hospitals at the beginning of 1933 there were 500 patients, so that the total number treated during the year was 14,154. It is of interest to note that in the year 1910 the total number of patients admitted was 7,494, which, with the number in the hospital at the beginning of the year—namely, 355—gave a total of 7,849 treated during the year. This great increase has been made possible by the use of the King Edward memorial block, which was begun before, and opened shortly after, the war, and the figures for the year which has recently closed, taken along with the formidable waiting list, provide the fullest justification for the appeal now being made. The number of patients admitted in respect of accidents and other emergencies was 2,083. Apart from these there were 2,580 admissions to the medical wards, 4,333 to the general surgical wards, 824 to the eye wards, and 1,812 to the aural department. To the beds reserved for skin cases 178 patients were admitted, and to the department for orthopaedics 1,235. For special radium treatment 446 patients were admitted into the wards. The figures dealing with patients suffering from affections peculiar to women require explanation; in 1932 they were 634 and in 1933 they were only 163. This, however, is due to the scheme of co-operation between the General Infirmary and the Hospital for Women having come into partial operation during the year upon which the figures are based. In future all such cases will be dealt with at the latter institution. The number of deaths occurring at the Infirmary was 823, which is a percentage mortality of six; when, however, the deaths which occurred within forty-eight hours of admission are deducted the mortality works out at 4.1 per cent. Under the superintendence of the senior officer of the West Riding Mental Hospital at Wakefield, an out-patient department was started during the year for patients with mental symptoms of a kind that do not demand or justify

certification. It is conducted by two of the assistant officers of the Wakefield Mental Hospital, and its progress will be watched with interest.

Mental Welfare Clinics in the Isle of Wight

During 1933 the mental welfare clinics at Newport and Ryde in the Isle of Wight dealt with 118 patients, of whom 102 came for the first time in that period. In comparison with the previous year there was a decrease in the number of those requiring to be certified, whilst the number entering the mental hospital voluntarily was doubled; this result is attributed to the co-operation that has been secured with local general practitioners, and the consequent larger proportion of early cases referred to the clinics for treatment. A large majority of the patients were in the first forty years of life; nineteen were of school age, and only three of these could be classed as definitely mentally defective. The clinics are thus shown to be functioning also to some extent as child guidance clinics; valuable preventive work is being accomplished, but it is felt that the clinics should be more concerned with adult neuroses, the children being dealt with elsewhere. Dr. C. Davies-Jones, medical superintendent of the County Mental Hospital at Newport, who has reported on these two clinics, adds to his statement a note on the suicide rate in the Isle of Wight during recent years. There were decided increases in 1931 and 1933. He thinks that in many cases suicide is a result of the urges of selfishness, while a minority appear to be psychologically, if not morally, justified. Incarceration is an unsatisfactory preventive; an attack on the determining factors, many of which are clearly economic in origin, would appear to be the better path to follow. Five cases were sent to the clinic in 1932, and seven in 1933, with suicidal wishes dangerously evident. At the time of reporting none of these had broken down. Dr. Davies-Jones doubts whether the publication of reports of suicides in the Press has much determining effect on causation; he believes there is an underlying psychological basis in these cases which requires attention and treatment. Anxiety states and hysteria are frequent, with purely psychological factors, or with such organic diseases as influenza; as an important complication. The critical age of 45 to 50 was prominent in female cases.

Local Government Officers.

The Report of the Departmental Committee appointed by the Minister of Health and presided over by Sir W. H. Hadow, to consider the recruitment, qualifications, training, and promotion of local government officers has now been issued. Under the heading of recruitment, the committee states that all vacancies for the local government service should be widely notified, so as to avoid any suspicion that appointments are being "jobbed," and the rule against canvassing should be strictly enforced. Candidates should be required to disclose whether they are related to a member or an officer, and where there is relationship the appointment should be closely scrutinized. Important recommendations with regard to the recruitment of professional and technical officers concern the system of articulated pupilage. On the question of technical qualifications, the committee doubts whether the officers responsible for giving technical advice to local authorities are in every case sufficiently well qualified, and concludes that a thorough investigation is needed. Finally, the committee urges the establishment of a standing central advisory committee to investigate and advise in all questions affecting the local government service. It regards the absence of such a central organization as "one of the most serious defects in the existing system."

Scotland

Edinburgh Municipal Hospitals

At a meeting of the Public Health Committee of Edinburgh Town Council on March 27th a report was submitted of the conference between representatives of the Corporation and Edinburgh University concerning the work of the municipal hospitals. A suggestion had been made by the directors of medical units in these hospitals involving a further expenditure of £775 per annum for additional staffing. It had already been agreed that the Corporation should pay to the University in respect of services of medical teachers provided by the University a sum not exceeding £2,000 per annum, and the actual amount paid in the past year had totalled £1,825. The Public Health Committee agreed that the figure of £2,000 should be increased to £2,500. A representation had been made by Dr. John Guy, medical officer of health, that certain alterations were desirable in the municipal general hospitals, and these had been estimated by the city architect to cost about £50,000. At the conference the University's representatives had suggested that instead of alterations a new general hospital should be erected to take the place of the three existing municipal hospitals, and, in view of this, further consideration of the alterations was delayed. The University had also proposed to establish a child welfare centre under the joint control of the Corporation and the University, and under the medical direction of the professor of child life and health, for the purposes of the supervision and care of healthy children, the clinical teaching of medical students and graduates in matters connected with the health of children, and the clinical investigation of problems concerning the health of infants and children. It was agreed that the University should be granted these facilities at one or more of the existing child welfare centres already established by the Corporation. The report of the medical officer of health stated that a careful survey of the future of the municipal hospitals should be made, having regard to the following: (1) better lecture-room accommodation; (2) provision of an operating suite; (3) additional small wards for paying patients; (4) reconditioning of the sanitary annexes; (5) installation of hand basins in the surgical wards; (6) rooms for the examination of new cases; (7) cubiculization of one surgical ward; (8) mortuary provision; (9) further provision for resident students; (10) provision of a nurses' home; and (11) open-air balconies for children's wards.

Larbert Institution for Mental Defectives

At the seventy-third annual meeting of the Royal Scottish National Institution at Larbert, the Earl of Mar and Kellie referred to the progress which had been made during the year in the construction of the colony for mental defectives. The administrative block had been erected, and there were now five houses with 150 inmates in the colony. The increase in population of the institution during the year had been seventy-nine, and it was hoped that money would soon be forthcoming to build a special hospital. Local authorities had recognized the value of the institution, and arrangements were being made with various councils to earmark a certain number of places for the mental defectives coming from each of the burghs concerned. Dr. R. D. Clarkson, medical superintendent of the institution, stated in his report that there had been 555 pupils on the register in February, 1933, and this number had increased by January, 1934, to 634. There had been 103 admissions during the year, fourteen discharges, and ten deaths. Expenditure amounted to £51,917, and a sum of £525 had been realized from work done by the inmates. Dr. Clarkson

said a stigma attached to mental deficiency because it was supposed that the condition was hereditary, but he had found that mental deficiency should not be regarded as a disease, and was seldom inherited. The greatest number of mentally defective children appeared in otherwise normal families.

Falkirk Infirmary

At the annual meeting of Falkirk and District Royal Infirmary Dr. John Young, chairman of the board, referred to the fact that a year ago the expenditure for the preceding year had exceeded the income by £1,000. The managers had then issued a special appeal, to which there was a very satisfactory response. During the past year the total income was £18,163, an increase of £1,013 over that of the previous year. The expenditure was £17,971, so that there was a surplus on the year's working. The endowment fund also increased from £23,689 to £25,353, while the total subscriptions from employees was £8,985, an increase of £562. The number of patients admitted to the wards during the year was 2,043 as compared with 1,555 in 1932, and the average number of beds in daily occupation was 116 as compared with ninety-three in the previous year. The average cost per patient per day was 7s. The total number of admissions to the maternity home was 304 as against 270 in 1932, and the average daily cost of the patients was 8s. 3d. The directors had acquired eleven acres of ground to the west of the Infirmary with a view to extension of the buildings.

Reports of Societies

CEREBRAL PNEUMOGRAPHY

A joint meeting of the Liverpool Medical Institution and the Manchester Medical Society was held at Manchester on March 7th, with Dr. C. PAGET LAPAGE, president of the Manchester Medical Society, in the chair.

Dr. HENRY COHEN read a paper on "Cerebral Pneumography." He emphasized that cerebral pneumography was based on two principles: (1) That no gross lesion can exist in the brain without deforming the fluid-containing spaces with resultant changes in their size, shape, position, and communication; and (2) that it is possible to replace the cerebro-spinal fluid by air, by either the lumbar route (encephalography), or the ventricular route (ventriculography), and thus visualize accurately by radiography the normal or deformed fluid spaces. He described in detail the methods he employed in both encephalography and ventriculography, and emphasized that the most notable contraindication to encephalography was the suspicion of a subtentorial tumour. Ventriculography was necessary to define the ventricular system, however, if any obstruction to the passage of air from the subarachnoid space to the ventricles was present. A large series of lantern slides were shown, illustrating the types of pneumographs obtained in cerebral tumours, epilepsy, degenerative lesions (including cerebral arteriosclerosis), and the traumatic encephalopathies. In only 25 per cent. of "tumour suspects" was cerebral pneumography required: occasionally, to differentiate vascular lesions and degenerative processes from expanding lesions, but more frequently to help in the localization of those cerebral tumours which showed no localizing signs or had given rise to false localizing signs. Dr. Cohen insisted that clinical examination must not be subordinated to pneumography; a careful anamnesis and physical examination could never be supplanted by mechanical procedures of this type, but cerebral pneumography had proved not only a useful and worthy addition to the diagnostic armamentarium of the physician, but it had thrown a flood of light upon the pathological basis of some of the epilepsies and traumatic "neuroses."

Immobilization of Fractures

Mr. R. WATSON JONES read a paper on "Inadequate Immobilization and Non-Union of Fractures." He said that recent enthusiasm for early mobilization and functional activity in fracture treatment was entirely justified, in that incapacity periods were reduced and many permanent disabilities avoided; but it should be recognized that joint mobilization must not interfere with absolutely complete and uninterrupted immobilization of the fracture. There was no more constant cause of non-union than inadequate immobilization. Hyperaemia of bone caused decalcification. If the initial hyperaemia of the trauma of injury was perpetuated by the frequently repeated trauma of movement of the fragments on each other, decalcification continued until a crack became a cavity, and a linear fracture became a gap fracture. Even slight movement, and especially rotatory movement, was sufficient to account for excessive decalcification. The Whitman plaster for fracture of the neck of the femur did not as a rule prevent rotatory movement of the pelvis and head of the femur, and for this reason, even in the 50 per cent. of cases which did unite when so treated, there was usually evidence of excessive decalcification in the shortening of the neck of the femur. On the other hand, a Smith-Petersen nail completely prevented rotatory movement, and in the speaker's series of twenty-eight subcapital fractures treated by operation over 90 per cent. had united. In fractures of the lower shaft of the ulna, non-union was due to attempted restoration of radio-ulnar movement after six or eight weeks of immobilization; before the fracture was consolidated. The radio-ulnar joint had become stiff, so that the movement could occur just as easily at the unconsolidated fracture as at the stiffened joint. For this reason, in three years the speaker had seen eighteen ununited fractures of the lower shaft of the ulna, although in every case the associated fracture of the radius—which was not subject to rotatory strain—had united. If these fractures were completely immobilized for the three or four months which were necessary to show radiographic evidence of consolidation, non-union never occurred. Fractures of the scaphoid bone in the wrist illustrated the same principle. Recent fractures usually united in six to eight weeks, but sometimes it was necessary to continue immobilization for many months, and if the institution of treatment was delayed, twelve to eighteen months of absolute immobility might prove necessary. If the surgeon was prepared to wait for it, bony union could be secured in practically every case. The speaker's conclusion was that whatever other factors might affect the union of fractures, non-union was only seen if immobilization was incomplete, or if it was not continued for a sufficient period.

PATHOLOGY OF FAT METABOLISM

At a pathological meeting of the Liverpool Medical Institution, held on March 22nd, with the president, Dr. J. MURRAY Blich, in the chair, Professor J. HENRY DIBLE read a paper on "Some Problems and Investigations in the Pathology of Fat Metabolism."

Professor Dible said that he wished to speak almost entirely of personal work which he had carried out during the past few years. A condition of fatty change was one of the most frequently encountered pathological conditions in certain organs, more particularly the liver, at post-mortem examinations in very diverse conditions. It was often seen in wasting diseases, such as infantile summer diarrhoea. This apparent anomaly was explicable upon an understanding of the changes which occurred in the liver fat in starvation. Experiments to elucidate this had shown that starvation caused a notable accretion of fat to the liver, but that the amounts infiltrating the organ were very variable and independent of the length of the starvation process. Careful quantitative investigations had shown that under similar conditions the quantity of fat infiltrating the liver in starvation was determined by the quantity of fat available in the

animal's storage depots. These results had been obtained in the first instance in the rat, but with Dr. Libman the same results had been shown in the rabbit. Since in most cases of disease an element of starvation occurred in the terminal stages, it might well be that this was a major factor in inducing the common fatty degeneration, equally with poisons or anoxaemia. This question had been investigated with the help of Dr. Gerrard, and a definite relationship established, in man, between the quantity of fat appearing in the liver and the degree of inanition present before death. In such cases a relationship had also been established between the degree of fatty infiltration and the adiposity of the subject.

Turning to the question of fatty degeneration of the heart, Professor Dible pointed out that in experiments carried out with Dr. Gerrard on phosphorus poisoning, a quantitative increase in fat in the degenerated cardiac muscle was constantly demonstrable. In work he had carried out upon the human heart in disease the same held good, very large increases being sometimes demonstrable and some increase, related to the histological picture, being constant. The significance of the histological changes in heart and liver showing fatty degeneration was discussed and the general conclusion given that in both organs fatty change was of the nature of an infiltration, there being no evidence for the existence of the process usually designated "phanerosis."

CORRESPONDENCE

Hereditary Scoliosis

SIR.—I am gratified to learn that Dr. Clement Belcher (March 31st, p. 596) has also observed familial scoliosis. As I said in my original paper my own cases were, to the best of my knowledge, the first to be recorded, though I have no doubt that the condition is not uncommon. Dr. Belcher's inferences, however, are a little startling, and I would suggest that he has allowed his ingenuity to triumph over common sense. He would have us believe that this anatomical abnormality can be acquired by both males and females of succeeding generations. But even assuming this strange hypothesis to be true, why invoke totally different environmental factors in each generation? Further, his imagination has accounted for scoliosis in three generations of women only, whereas in my pedigree men and women were affected in equal proportions.

The statement that "if the condition were hereditary we should expect the malformation to be still more marked in the third generation" makes one question Dr. Belcher's knowledge of human genetics very seriously. If an inherited abnormality increased from one generation to the next it would soon become lethal and self-limiting, which is clearly not the case with Mendelian dominant defects. In point of fact such inherited defects always show varying grades of severity, and in any generation there may be cases which merge into the normal. I would like to point out that, far from the condition being "practically absent, or, at any rate, not a noticeable deformity" in the third generation, my case, D.I.S, that of a female aged 32 and of the fourth generation, did not know of her deformity until I pointed it out, but a brother and two sisters were known to have been affected from birth.

When a skeletal defect occurs in five generations, affecting males and females equally, the ratio of affected to unaffected offspring of an affected parent being approximately 1 : 1, the condition is inherited as a Mendelian dominant, and one can forecast with reasonable accuracy that in the future half the children of affected parents will themselves be affected, despite any variable environmental factor.—I am, etc.,

Leeds, April 3rd.

HUGH G. GARLAND.

Pathogenesis of Cancer

SIR,—In the *Journal* of February 24th Mr. Frank Paul out of his life-long clinical experience and special knowledge of the surgery and pathology of cancer, contributes an interesting and instructive communication upon this subject, and emphasizes from his observations the existence of a natural control or suppression of growth, exemplifying this process in various cases. On March 31st another correspondent, "M.D.," from his clinical observations, suggests this aspect of the cancer problem to be one of biochemistry, and that "a lead from Nature" is urgently needed.

During the past thirty years numerous investigations have shown the presence of biochemical factors in the blood, which suggest that there is always present in normal persons an active and efficient natural control or prevention of cancer, and that in those who develop the disease these essential defensive factors are deficient. The observations and findings of these observers seem to be strangely forgotten, and the possible importance of their clinical application to the cancer problem overlooked. Shaw-Mackenzie, in no fewer than twenty-two papers and communications between 1905 and 1931, Freund in 1913, Corran and Lewis in 1928 (confirming Shaw-Mackenzie's work), Begg and Aitken in 1932, and Green in 1934, have all shown, either in experimental animal research or in clinical serological investigations, that the presence of cancer or its recurrence after removal, is almost invariably associated with a deficient lipolytic or fat-splitting enzyme content of the blood, and, conversely, that recovery from cancer, either after removal of the growth or by regression or occasional spontaneous cure, is associated with a recovery of the normal lipolytic activity of the serum. Vernon in 1905, von Leyden and Bergell in 1907, Marcus, Breiger, and Trebing in 1908, similarly have shown changes from the normal in the proteolytic enzyme content of the blood. By demonstrating the constant presence of active biological agents in normal blood and their deficiency in the serum of those that develop cancer, all observations suggest that these are natural defensive enzymes. Bendien in 1931 introduced a blood test for cancer, which Begg and Aitken in 1932 showed to give parallel findings to those of Shaw-Mackenzie's test in experimental animals. I modified Bendien's test (1933), and find that both in animal experiments and in numerous clinical observations it gives, because of the presence of abnormal alterations in the protein and lipid content of the serum, indirect but equally clear evidence of deficiency in the serum of cancer cases of those essentially necessary protective and controlling enzymes.

It is generally accepted that cancer results from some form of damage and irritation of normal cells. Such injury may be traumatic, whether physical, thermal, chemical, electrical, or radiological, etc.; infective, whether bacterial, protozoal, or viral; or due to toxic or senile changes. Cramer and Bullock (1919), Warburg (1923), Ewing (1929), Kreyberg (1929), and Sampson Handley (1930) have all demonstrated various bio-physical, biochemical, and pathological alterations that occur in, or accompany the conversion of, an injured normal cell into what Blair-Bell so aptly describes as a dedifferentiated cell—a trophoblastic cancer cell. This does not, however, explain why, as these "accidents" to cell life are so common, only about 15 per cent. of people develop cancer. Why do we not all die of cancer; for who, if he lives long enough, does not suffer the results of trauma, infection toxicity, etc.? This question is, however, answered by admitting that there is present, in the 85 per cent. who remain cancer-free, a natural cancer-cell-destroying agency, and it is the deficiency of this factor which allows cell injury and irritations, etc., to result in cancer in the unfortunate ones.

In the *British Journal of Radiology* (April, 1933) I gave reasons for assuming that such a natural cytolytic defence exists. As a working hypothesis, the embryo-

logical observations of Teacher, Bryce, Fairbairn, etc., and the suggestions of Blair-Bell (1924), have been adopted as providing at present the most satisfactory explanation of the problem of cancer, and divide life for this purpose into intrauterine and post-natal experiences. In the former the differentiating somatic cells of the unborn foetus during its earlier months of existence are successfully inhibiting, controlling, correlating, cytolysing, and finally converting the previously invasive, erosive, "malignant-like" undifferentiated chorion epithelium into the inert physiological placental membrane found at full term, so that at birth presumably every infant starts life having learnt in its mother's womb the way to control, suppress, and destroy undifferentiated trophoblastic cells. In about 85 per cent. this invaluable heritage of cytolytic defence remains good throughout life, so that whenever as the result of tissue injury somatic cells revert by dedifferentiation to the trophoblastic type, with their abnormal contents (highly lipoidal, hydrophilic proteins, increased water content, and cell membrane permeability), the normal somatic tissues are as able efficiently to cytolysise these new-formed would-be cancer cells as their predecessors dealt with undifferentiated chorion epithelium in the pre-natal period. In the other 15 per cent., although efficiency may continue nearly normal for the first thirty years of life, in the subsequent decades a loss in cytolytic defence sooner or later develops, and the associated inability efficiently to control or destroy dedifferentiated cells when they occur is demonstrated by the increasing liability to cancer developing in these later years. Thus will be explained the infrequency of cancer during earlier life and the well-known age-incidence in the middle and later decades, also the recognized tendency to its increase under modern civilized conditions; for failure of a natural endocrine, enzymic, hormonal function might be expected when the strains and stresses of life tend to be most exhausting.

The serum tests of Shaw-Mackenzie and Bendien frequently show variations from, and recovery of, normal findings, and it is quite feasible that in certain cases a temporary lapse of cytolytic defence may have allowed of the development of cancer, but the re-establishment of normal control caused arrest and regression or even spontaneous cure of the growth. Further, as a result of repeating blood tests upon a number of cases of cancer, it is often found that in spite of a temporary return to a normal, defensive efficiency, as the result of surgery, radium, etc., the enzymic content is not maintained—in some cases quite shortly, while in others not for a year or two, and presumably in some only after five, ten, or more years—the regained defence again fails, and recurrence, metastasis, or a new primary cancer may develop.

The work of Gye with regard to the presence of a specific virus, and of Schmidt, Sambon, and others, of protozoa, all need consideration as providing evidence of possible specific causes of somatic cell dedifferentiation, but their importance as causal agents of cancer will depend upon the presence or absence of an efficient cytolytic defence in the blood of the person whose tissue cells are being stimulated to abnormal activity. Many research workers have shown that the result of artificial lysis of cancer tissue *in situ*, whether from diathermy, radium, x rays, lead, sodium oleate, etc., raises the enzymic efficiency of the serum, and confers a certain degree of immunity, while Professor Russ (1933) has suggested that the result of radiation in cancer treatment may produce a generalized somatic stimulation apart from its local effect, and the improvement in the serum tests following such treatment suggests that successful and graduated cytolysis is associated with a defensive endocrine stimulation.

Even in this scanty review of the large amount of serological and other research referred to above, it would appear, that the "lead from Nature" as regards the prevention and cure of cancer suggests the need of discovering how to maintain effectively a normal cytolytic defence in those whose serum shows it to be deficient. From this point of view cancer appears as

a deficiency disease, somewhat in line with pernicious anaemia and diabetes, but instead of being a deficiency of metabolic supply for normal cell life, as in the latter, it seems to depend upon a deficiency in the power to inhibit or destroy cells of a certain embryonic type. This normal controlling factor is likely to be complex, may be a hormonal secretion to which all normal tissue contributes, or may be supplied by a group of endocrine glands such as the pituitary, adrenals, thyroid, and liver. It thus becomes a problem for the biochemist and pharmacist to show how an efficiency can be maintained, and thereby support and enhance the result of local removal or destruction of malignant growths.—I am, etc.,

Liverpool, March 31st.

E. CRONIN LOWE.

Leucocyte Counts

SIR,—Your editorial in the *British Medical Journal* of March 31st (p. 586) on the normal leucocyte count quotes largely from a paper by Simpson (*Brit. Journ. Radiol.*, 1933, vi, 705), which is claimed to confirm the work of Sabin and her co-workers, purporting to demonstrate large fluctuations in normal leucocyte counts. It appears to have escaped the notice of the writer of the editorial and Dr. Simpson that Sabin's results have been shown by Ponder, Saslow, and Schweizer (*Quart. Journ. Exper. Physiol.*, 1931, xxi, 21) to have been due to technical error. After a detailed study of technique by statistical and experimental methods these workers found that normal fluctuations were less than ± 8 per cent., apart from the well-known afternoon rise. Sabin counted generally 100, and occasionally 200, cells. Simpson counted the cells in 1 c.mm. of blood diluted 100 times, so that where the counts were 3,000 and 6,000 per c.mm. of blood he would count only thirty and sixty cells respectively. It is doubtful, therefore, if the conclusions stressed in your editorial are justified. In the standard methods of the Association of Clinical Pathologists the cells in three times the above amount of blood are counted, and in this laboratory, in routine clinical work, about 400 cells are usually counted. I should be surprised, therefore, if Simpson's counts are "leucocyte counts performed in the usual way."

It is of interest that similar claims have been published from time to time for normal fluctuations in other blood constituents, such as platelets and sugar content, which have subsequently been shown to be due to defective technique, in spite of the fact that a few preliminary experiments have been stated by the authors to show that the technique gave reliable results. Such papers have been encountered sufficiently often in the past to raise immediate doubt in the present instance as to the accuracy of the technique employed. The tone of your editorial appears to me unfortunate, in view of the relative backwardness in the application of haematology in this country as compared with America and Germany. This is strongly suggested by the paucity of recorded cases in England of agranulocytic angina, which even technically defective leucocyte counts can scarcely fail to demonstrate if employed at all.—I am, etc.,

Bradford Royal Infirmary, April 5th.

C. J. YOUNG.

SIR,—There are few clinicians, one would imagine, who would accept as final the conclusions drawn in your leader of March 31st, on the subject of the normal leucocyte count, unless it is understood that these conclusions refer only to non-febrile conditions. Though one is aware that it is the normal count which is discussed, still, without a normal, one is left to conclude that the so-called abnormal counts may be included in such strictures as are made on some clinicians' reliance on laboratory reports.

Without a knowledge of the exact method used, one may perhaps be allowed to suggest that the method of faking blood from the fingers, as is mentioned, may, unless all constriction be avoided, which is difficult, to some extent explain the discrepancy obtained in the figures noted. During a research into possible variations in the leucocyte count during abnormal mental states made some years ago, taking blood only from the lobe of the ear and with the minimum of pressure, one found that the variations were so small as to warrant no conclusions being drawn therefrom, and though counts were made daily (not necessarily at the same hour in the same individual), no such discrepancy as was noted by Simpson was found in the figures obtained. Method apart, clinical experience surely does show that in many febrile states the leucocyte count is affected on the average in a definite direction for each disease, and that, for example, in influenza, typhoid, measles, whooping-cough, and septic conditions generally, the trend of the leucocyte count is of the utmost value in early diagnosis before the other signs and symptoms may be present. This, of necessity, leads one to inquire if it is possible that, though there may be no normal average in health, in disease—particularly febrile disease—the figures for each diseased state are more constant.—I am, etc.,

London, N.7, April 8th.

W. LEES TEMPLETON, M.D.

Radiology and Chronic Appendicitis

SIR,—With reference to Dr. C. H. C. Dalton's letter in your issue of February 24th (p. 353), following Mr. Muir Dickson's article on the diagnosis of chronic appendicitis in the *Journal* of February 3rd (p. 184), may I be permitted to add that much has been written on this subject about the direct and indirect radiological signs of the disease of the appendix, and often due emphasis has not been laid on the possibility of the coexistence of associated duodenal or gall-bladder disease. It is true that Mr. Muir Dickson alludes freely to the clinical difficulties of the differential diagnosis, but he does not suggest the obvious remedy.

Realizing the great value that x-ray examination has become as a diagnostic aid in so many and varied pathological conditions, it seems only right as a first step to examine our methods of examination of the appendix to see if any fault can be found there. I will deal with this subject from two aspects: (1) the failure to discover that the appendix is pathological; and (2) the failure to recognize that the pathological changes discovered may not be the cause, or the sole cause, of the patient's symptoms.

1. The identification of the barium-filled appendix is essential to the diagnosis, and, as Dr. Dalton points out, this means careful preparation of the patient. This is best done, in my opinion, by administering a laxative thirty-six hours before the examination, and not by giving castor oil twelve hours beforehand, as he suggests; for a drastic purge taken at so short a time before the meal is likely to give a false impression of the motility of the meal, which latter may be an important indirect sign of disease. Stasis of barium in the appendix does not appear to be of any great significance *per se*, and I have seen lead shot remain in the appendix for many weeks before passing on. In cases in which the caecum is placed abnormally low it is often not possible to identify the appendix, and it is certainly impossible to palpate it satisfactorily until it is dislodged from its position in the pelvis. In these cases attempts may be made to dislodge the caecum from its abnormal position by sustained pressure in the left iliac fossa; should this fail the patient may be tilted into the Trendelenburg position. In obstinate cases the knee-elbow position can be tried, or the rectum may be distended with air by a Higginson syringe; or, finally, the patient may be given copious fluids

and asked not to empty the bladder. The x-ray investigation of the appendix is primarily fluoroscopic, but often the appendix can be demonstrated on subsequent radiograms, taken as a rule while palpating the right iliac fossa with a gloved hand to hold the parts in the optimum position. The most reliable sign of chronic inflammation is tenderness localized over the filled appendix; but in its absence—and it is important to be sure that such tenderness is real—there may be found to be permanent kinks or constrictions, bulbous deformities, faecoliths, or evidence of adherence to the colon or small bowel. The appendix may be discovered in any relation to the caecum, and the caecum may be situated in any position between the right hypochondrium and the left iliac fossa.

2. In connexion with the failure to recognize that the pathological changes discovered may not be the cause, or the sole cause, of the patient's symptoms, I would stress Dr. Dalton's plea for the importance of a thorough examination of the stomach and duodenum owing to the not infrequent association of duodenal ulceration, or duodenitis, with chronic inflammation of the appendix. Of even greater importance and frequency is the association of cholecystitis, or biliary calculi. So much so, that I feel that the radiological investigation of the appendix is incomplete unless the gall-bladder is also examined after dye. This fact probably also accounts for the recent publications from abroad to the effect that the Graham-Cole test may fail to fill the gall-bladder in cases of duodenal ulcer and chronic appendicitis.

I can recommend investigation by barium prior to operative procedure: (a) if only to show the position of the appendix (and this may have a direct bearing on the type of incision to be made for its removal); (b) to discover abnormalities of the appendix as shown by alteration in the shape of its lumen; and (c) to exclude the possibility of associated gall-bladder or duodenal pathology. But until the gall-bladder dye test is made a part of the routine, appendicectomy may never give 100 per cent. satisfactory surgical after-results.—I am, etc.,

London, W 1, March 9th.

J. V. SPARKS.

Raised Intraocular Tension

SIR,—I have to thank Dr. Victor Purvis very much for his interesting commentary (February 3rd, p. 215) on my article in your issue of January 20th (p. 102) on increased intraocular tension. I regret that my use of the words "was thought to be higher" led him to think that my colleagues and I were actually in doubt about the existence of increased intraocular tension in these cases. That was not my intention. Reference to the case notes themselves would seem to make that quite clear.

If we accept, then, that the tension was raised we are brought at once into direct conflict with Dr. Purvis's contention that, if we can be sure by digital tonometry that the tension is raised, "then, of course, there would be other indubitable signs of glaucoma." In my cases these signs were absent, and that was the whole point of the article—namely, the existence of pathological hypertension which could not reasonably be called glaucoma in the absence of the other signs, a description of some of its signs and symptoms, and an inquiry whether such a syndrome has been recognized previously. I have had two more cases of my own, and Lieut.-Colonel Jack, I.M.S., of Sialkot, has just written to me about one he has recognized—that of a medical student who has been the round of the clinics in a big medical school in India, and had his antra explored without relief to his left frontal and temporal headache. Lieut.-Colonel Jack and a colleague diagnosed this as due to increased intraocular tension, and relieved it in forty-eight hours by the use of eserine. The patient had previously been

diagnosed as a case of trigeminal neuralgia, and had taken large doses of analgesics. The four patients reported on originally have had no further attacks.

I still stick to my guns in the face of Dr. Purvis's reasoned scepticism, and hope for further enlightenment, especially in relation to cause.—I am, etc.,

R. L. RAYMOND,
Flight Lieutenant R.A.F.M.S.

Ambala, March 20th.

Barbiturate Poisoning

SIR,—The following case illustrates the cumulative effect of repeated doses of the barbiturate group of drugs.

A man, aged 62 years, apparently in good health, was admitted to the Royal Victoria Hospital, Belfast, suffering from a fracture of the neck of the left femur. An operation was performed by Mr. S. T. Irwin on March 16th. This consisted in manipulation and fixation of the leg in position with plaster. The patient was given five capsules of sodium soneryl (0.75 gram) by mouth at 12 noon. [Soneryl is butyl-ethyl barbituric acid.] About one hour later he was very drowsy. He was then anaesthetized with ether, very little of which was needed. The duration of the anaesthesia was about ten minutes. In the evening he was still drowsy. He awakened during the night and complained of the discomfort of the plaster, and as he did not settle down he was given two tablets of soneryl (3 grains). Soon afterwards he became comatose, with infrequent shallow respirations and weak pulse. Cyanosis was marked. Some improvement in the pulse followed the injection of 2 c.cm. of coramine. Further treatment consisted in inhalations of carbon dioxide periodically, strychnine 1/30 grain, and more coramine. During the following day consciousness gradually returned and his general condition improved. He has made a good recovery.

—I am, etc.,

Belfast, March 26th.

STAFFORD GEDDES.

The Election to the Council of the Royal College of Surgeons

SIR,—In April, 1928, you published a letter of mine giving my views on the utility of the canvassing in vogue for this election. I was grateful because I was subsequently left in peace until some two years ago, when I received a mass-production letter from a body of gentlemen who happened at that time to be examining together. As far as I can remember, it was to the effect that the salvation of the College and my own could only be assured if one of their number was elected to the Council, that they had selected Mr. X for this purpose, and that it was my duty to vote for him. I can only suppose that my salvation is still in jeopardy.

Since then I have heard rumours of the pooling and bartering of votes, in London and out of it. But as I have no personal knowledge of this and have not been invited to become a member of any caucus with this object in view, I make no comment other than to say that I hope the rumours are without foundation.

But now the private begging-letter writer has cropped up again. I have recently received a communication which appears on the surface to be a personal, though typewritten, letter. Closer investigation reveals it to be printed in the form of typescript, presumably in sufficient numbers to circulate every Fellow of the College. My name and the suggestion that I am "Dear" have been added at a later date with a typewriter. This letter enumerates the good qualities of a gentleman who is well known to me. It goes on to point out that a hospital, other than my own, is at the moment unrepresented on the Council, a situation which appears to

a deficiency disease, somewhat in line with pernicious anaemia and diabetes, but instead of being a deficiency of metabolic supply for normal cell life, as in the latter, it seems to depend upon a deficiency in the power to inhibit or destroy cells of a certain embryonic type. This normal controlling factor is likely to be complex, may be a hormonal secretion to which all normal tissue contributes, or may be supplied by a group of endocrine glands such as the pituitary, adrenals, thyroid, and liver. It thus becomes a problem for the biochemist and pharmacist to show how an efficiency can be maintained, and thereby support and enhance the result of local removal or destruction of malignant growths.—I am, etc.,

Liverpool, March 31st.

E. CRONIN LOWE.

Leucocyte Counts

SIR,—Your editorial in the *British Medical Journal* of March 31st (p. 586) on the normal leucocyte count quotes largely from a paper by Simpson (*Brit. Journ. Radiol.*, 1933, vi, 705), which is claimed to confirm the work of Sabin and her co-workers, purporting to demonstrate large fluctuations in normal leucocyte counts. It appears to have escaped the notice of the writer of the editorial and Dr. Simpson that Sabin's results have been shown by Ponder, Saslow, and Schweizer (*Quart. Journ. Exper. Physiol.*, 1931, xxi, 21) to have been due to technical error. After a detailed study of technique by statistical and experimental methods these workers found that normal fluctuations were less than ± 8 per cent., apart from the well-known afternoon rise. Sabin counted generally 100, and occasionally 200, cells. Simpson counted the cells in 1 c.mm. of blood diluted 100 times, so that where the counts were 3,000 and 6,000 per c.mm. of blood he would count only thirty and sixty cells respectively. It is doubtful, therefore, if the conclusions stressed in your editorial are justified. In the standard methods of the Association of Clinical Pathologists the cells in three times the above amount of blood are counted, and in this laboratory, in routine clinical work, about 400 cells are usually counted. I should be surprised, therefore, if Simpson's counts are "leucocyte counts performed in the usual way."

It is of interest that similar claims have been published from time to time for normal fluctuations in other blood constituents, such as platelets and sugar content, which have subsequently been shown to be due to defective technique, in spite of the fact that a few preliminary experiments have been stated by the authors to show that the technique gave reliable results. Such papers have been encountered sufficiently often in the past to raise immediate doubt in the present instance as to the accuracy of the technique employed. The tone of your editorial appears to me unfortunate, in view of the relative backwardness in the application of haematology in this country as compared with America and Germany. This is strongly suggested by the paucity of recorded cases in England of agranulocytic angina, which even technically defective leucocyte counts can scarcely fail to demonstrate if employed at all.—I am, etc.,

Bradford Royal Infirmary, April 5th.

C. J. YOUNG.

SIR,—There are few clinicians, one would imagine, who would accept as final the conclusions drawn in your leader of March 31st, on the subject of the normal leucocyte count, unless it is understood that these conclusions refer only to non-febrile conditions. Belfast, March 26th.

STAFFORD GEDDES.

The Election to the Council of the Royal College of Surgeons

SIR,—In April, 1928, you published a letter of mine giving my views on the futility of the canvassing in vogue for this election. I was grateful because I was subsequently left in peace until some two years ago, when I received a mass-production letter from a body of gentlemen who happened at that time to be examining together. As far as I can remember, it was to the effect that the salvation of the College and my own could only be assured if one of their number was elected to the Council, that they had selected Mr. X for this purpose, and that it was my duty to vote for him. I can only suppose that my salvation is still in jeopardy.

Since then I have heard rumours of the pooling and bartering of votes, in London and out of it. But as I have no personal knowledge of this and have not been invited to become a member of any caucus with this object in view, I make no comment other than to say that I hope the rumours are without foundation.

But now the private begging-letter writer has cropped up again. I have recently received a communication which appears on the surface to be a personal, though typewritten, letter. Closer investigation reveals it to be printed in the form of typescript, presumably in sufficient numbers to circulate every Fellow of the College. My name and the suggestion that I am "Dear" have been added at a later date with a typewriter. This letter enumerates the good qualities of a gentleman who is well known to me. It goes on to point out that a hospital, other than my own, is at the moment unrepresented on the Council, a situation which appears to

cause acute distress to the writer. But such is his *naïveté* that he does not explain why I should regard it with equal misgiving.

The statements about the gentleman in question, who is a wholly admirable person, are in fact true. But that does not affect my point of view. I resent the implication that I am unable to make up my so-called mind about the disposal of my votes without the help of others; and I deplore the introduction of pseudo-political methods into the election to a body so august as the Council of the Royal College of Surgeons of England. If we cannot conduct the election with the dignity to which it is entitled, why should we not go the whole hog? Why should not each candidate issue a manifesto over his own signature, proclaiming his merits, adducing the benefits which would accrue if he were successful, and exposing the imperfections of his competitors?

In the meantime, I shall adhere to my policy of withholding my vote from any candidate on whose behalf I am vicariously assailed by his friends or colleagues. —I am, etc.,

London, April 7th.

IVOR BACK.

The Tuberculosis Problem

SIR,—Many tuberculosis workers will, I believe, be interested to learn from Dr. Waldron (March 31st, p. 598) the names of those who have stated "authoritatively" that "adult infection is impossible," and that "tuberculosis constitutes no problem in the school child." Tuberculosis is an interesting study at all ages and in all places. If Dr. Waldron will consult pages 64 to 69 of Dr. J. B. McDougall's report on the British Legion Village for the year ending September, 1933, he will find the subjects of conjugal infection and disease, childhood infection and disease, and Mantoux tests adequately discussed. The great majority of tuberculosis officers use the Mantoux test when they consider it will help them. I have used it regularly in the clinical examination of children for many years, and occasionally in adults, correlating the test with my x-ray findings.

Dr. Waldron states that the tuberculosis officer suffers "the explicable contempt of the general practitioner." Well, perhaps some of us have deserved that fate. But our experience in the North and West has not been so humiliating. When a case of disease of the chest is referred to me by a general practitioner I do not let it go until a diagnosis has been established, even if this sometimes involves my trespassing on the time and kindness of my friends in the London chest hospitals, when the necessary technical investigations are beyond the powers of our own organization. Out of my last 1,500 cases referred by general practitioners, over 53 per cent. proved to be suffering from non-tuberculous conditions. In Wales and in Lancashire the proportion of non-tuberculous cases referred for diagnosis by general practitioners is even higher. It is our business to diagnose the cases, and to indicate, and, when practicable, to carry out, treatment—not merely to write a chit: "No evidence of active tuberculosis."

Treatment would appear not to enter into the consideration of Dr. Waldron. Our enlightened public authorities now provide hospital beds, which are in charge of their tuberculosis officers. In Wales medical men in the tuberculosis service take district work and institutional work in turn. And our sanatoria are true "chest hospitals." As Dr. David Stewart of Manitoba says: "The days of the shack sanatorium are over."

During the year 1932, according to Sir George Newman's report, the certified causes of death per 1,000 deaths from all causes in this country were as follows:

	Per 1,000 deaths
Diseases of the heart and circulatory system	264
Malignant disease	125
Bronchitis, pneumonia, and other respiratory diseases	113
All forms of tuberculosis	69

There is obviously scope for those medical men who specialize in diseases of the chest.

Finally, suppose Dr. Waldron's Mantoux survey undertaken. We can safely forecast from our present accumulated knowledge that the positive reactors would vary from at least 50 per cent. positives in congested cities to nil in certain isolated rural areas. What does Dr. Waldron suggest should be done with the positive reactors—pole-axe them, isolate them, or banish them from the country?—I am, etc.,

P. HEFFERNAN, M.D.,

Tuberculosis Office, Derbyshire County
Council; President, North-Western
Tuberculosis Society.

Buxton, April 2nd.

SIR,—May I enjoy the hospitality of your columns once more to epitomize this correspondence since my original letter and to elaborate slightly some of the points raised therein? The hornets have buzzed and we have learned the particular sting of each; let us hope that they will not be content to settle into their nest again. The correspondence has gone a little off the rails at times; the majority are agreed, however, that anti-tuberculosis organization in this country is very imperfect, and it would not seem that lack of adequate finance is entirely to blame.

The profession is evidently uneasy. It is apparent that there are good and bad tuberculosis dispensaries. Why? It is fairly obvious that this must be due to a misapplication of those bureaucratic principles which we all hate, but which are, nevertheless, a necessary evil in modern scientific organization. It seems to me that what is required is more co-ordination between the various local authorities responsible for these dispensaries, with a supreme authority, say, the Ministry of Health, in ultimate control. Impartial inspectors could then visit the various areas and ensure that the standard of efficiency would be uniform—the best. Thus, the anomaly of "E. N. R.'s" prayer for patients and mine for assistance might be removed. Visits would be made to all centres, official and otherwise, and details of the methods of each, proved good by the results, collected and adopted by all.

Dr. Camac Wilkinson's letter is full of sound common sense, but in thanking him for his invitation may I point out that any clinics organized in opposition to those existing would be courting failure without the moral and financial backing of the Government. The organizers must get a living wage from somebody, and their jobs would necessarily be whole-time. Adaptation of the present system would be surer of success, and would also enable the disciples of blood sedimentation, complement-fixation, Mantoux, etc., to offer their contribution as well as the champions of tuberculin.

It is too much, I presume, to hope that the Ministry or other authoritative body will take the initiative in this matter, so I appeal to the profession at large to give the necessary punch to a campaign for improvement. For my part I am proposing to make representations on the lines of this correspondence to our chief tuberculosis officer and to the Minister of Health himself, when I can find the time.—I am, etc.,

Greenford, April 4th.

ALISTAIR R. FRENCH.

* This correspondence is now closed.—ED., B.M.J.

BRITISH EMPIRE CANCER CAMPAIGN

In the absence of Lord Reading, Sir HOLEBURT WARING, President of the Royal College of Surgeons, presided at the quarterly meeting of the Grand Council of the British Empire Cancer Campaign, held at 12, Grosvenor Crescent, on April 9th.

A report was received from the judges concerning the essays on "The Biological Effects and Mode of Action of Radiations upon Malignant and other Cells" which had been submitted in connexion with the Garton Prize of £500 and gold medal. It was decided that the prize of £500 and the gold medal should be awarded to Dr. H. A. Colwell, M.R.C.P., D.P.H. As one of the other essays was of such high merit, Grand Council, under the rules and regulations, decided that a second award of £100 should be made to its authors, Dr. F. G. Spear in association with Dr. R. G. Canti, Mr. L. G. Grummett, Dr. B. Holmes, Miss S. F. Cox, and Dr. W. H. Love.

The following were elected members of the Grand Council and of the Executive Committee of the Campaign: Sir Frederick Menzies, medical officer of health to the London County Council; Sir Peter Chalmers Mitchell, secretary to the Zoological Society; Mr. W. H. Ogilvie, assistant surgeon to Guy's Hospital; Captain Ian Fraser, M.P., chairman of the executive council of St. Dunstan's; Sir Frederick Hobday, principal and dean of the Royal Veterinary College; Dr. Malcolm Donaldson, gynaecologist to St. Bartholomew's and Mount Vernon Hospitals; and Mr. Eric L. Pearce Gould, surgeon to the Middlesex Hospital.

A grant of £150 to the Holt Radium Institute, Manchester, for the part-time services of Dr. R. McWhirter for the purpose of the continuation of his cancer research, was confirmed.

A report was received that the meeting convened by the Lord Mayor of London, to be held at the Mansion House on May 1st, in aid of the Empire Day Appeal, would be attended by H.R.H. the Duke of York, President of the Campaign, who will be supported by Sir Hilton Young (Minister of Health), Lord Reading (chairman of the Grand Council), Lord Dawson of Penn (President of the Royal College of Physicians), Sir Holburt Waring (President of the Royal College of Surgeons), Lord Horder of Ashford (chairman of the Scientific Advisory Committee), Lord Moynihan of Leeds (Past-President of the Royal College of Surgeons), Sir Charles Gordon-Watson, Sir Richard Garton, and other members of the Grand Council. Lord Moynihan will make a broadcast appeal on Sunday, May 20th, throughout the British Empire. Apart from the flag day to be held in the metropolitan area and the City of London, over 700 centres at home and over-seas are co-operating in a series of flag days, house-to-house collections, and similar activities.

Universities and Colleges

UNIVERSITY OF LONDON

UNIVERSITY COLLEGE

Bayliss-Starling Memorial Scholarship

This scholarship has been founded by old students, friends, and admirers in commemoration of Professor Sir William Maddock Bayliss and Professor Ernest Henry Starling. Its annual value is about £120, with exemption from tuition fees, and it is tenable at University College, London. The scholar will be required to follow a course of study approved by the Jodrell Professor of Physiology, involving a training in the principles of, and methods of research in, physiology and/or biochemistry. Candidates must send their applications to the secretary of University College (Gower Street, W.C.1) not later than May 12th.

Bucknill Scholarship

The examination for the Bucknill Scholarship, value 160 guineas, and for two exhibitions, value 55 guineas each, will begin on May 14th. The subjects for the examination are chemistry, physics, botany, and zoology. The scholarship and the two exhibitions are tenable at University College, London. Entry forms should be obtained from the secretary of University College (Gower Street, W.C.1), and returned not later than April 27th.

UNIVERSITY OF ABERDEEN

The following degrees were conferred on April 4th:

Hon. LL.D.—Herbert Ritchie Spencer, M.D., F.R.C.P., Emeritus Professor of Obstetric Medicine, University of London.
D.Sc.—Captain Hugh Waddell Mulligan, M.D., I.M.S. (*in absentia*).

M.D.—W. C. Davidson (*in absentia*), *F. Hunter, D. Duncan, A. D. Macdonald.

M.B., Ch.B.—P. H. R. Anderson, H. S. Brady, W. M. Davidson, D. J. Fraser, R. S. Garden, W. N. Gilchrist, Mary E. Harrow, H. McB. Henderson, Marjory I. Lawrence, G. G. Lennon, A. MacLennan, J. D. MacLennan, J. S. MacKae, A. M. Mair, G. C. Milne, G. P. Milne, J. P. Milne, Rosalind M. P. Milne, J. R. Mutch, M. J. Schultz, W. Stewart, J. C. Thom, D. Wilson, J. S. M. Wilson.

* Commended for thesis.

UNIVERSITY OF ST. ANDREWS

The Senatus Academicus has resolved to confer the honorary degree of LL.D. on Sir Frederick Gowland Hopkins, Sc.D., F.R.C.P., President of the Royal Society, and Professor of Biochemistry in the University of Cambridge; and on Lord Moynihan of Leeds, K.C.M.G., C.B., F.R.C.S. The graduation ceremony will be held on June 29th.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly meeting of the College, held on April 6th, J. F. Cunningham, A. G. Thompson, G. C. Dockeray, and A. H. Thompson were admitted to the Fellowship.

Professor T. G. Moorhead, past-president, was elected to the office of President of the College for the remainder of the current academic year.

The president nominated Dr. William Boxwell as vice-president of the College.

The following successful candidates at the Conjoint Final Examination with the Royal College of Surgeons in Ireland were admitted to Licences in Medicine and Midwifery: D. T. Broolly, Marie T. Carton, W. A. Cavanagh, J. A. Dorrán, K. A. Evans, J. Hempenstall, T. P. Murray, Augustine McGennis, P. McKenna, K. G. Reynolds, S. A. Segal, P. J. Shields.

The Services

INDIAN MEDICAL SERVICE DINNER

The annual dinner of the Indian Medical Service will be held at the Trocadero Restaurant, London, on Wednesday, June 20th, at 7.15 p.m. Major-General Sir Leonard Rogers, K.C.S.I., C.I.E., F.R.S., will preside. Tickets and all particulars may be had from the joint honorary secretary, Sir Thomas Carey Evans, Hammersmith Hospital, Ducane Road, W.12.

HONORARY PHYSICIAN TO THE KING

Brevet Colonel J. W. L. Scott, D.S.O., R.A.M.C., has been appointed Honorary Physician to the King, vice Lieutenant-General Sir Harold B. Fawcus, K.C.B., C.M.G., D.S.O., who has retired.

DEATHS IN THE SERVICES

Surgeon Commander Samuel Conner, R.N. (ret.), died at Twyford, near Winchester, on March 18th, aged 61. He was the youngest son of the late Daniel Conner, Royal Marines, of Ballybricken, County Cork, was educated at Queen's College, Cork, and graduated M.B., B.Ch., and B.A.O. of the Royal University, Ireland, in 1896. Entering the Navy soon after, he reached the rank of surgeon commander on May 26th, 1913. He served throughout the war of 1914-18.

Surgeon Commander Robert Howard Nicholson, R.N. (ret.), died at Blackheath on March 19th. He was the son of the late Captain Huntly Nicholson, Grenadier Guards, was educated at the London Hospital, and took the M.R.C.S., L.R.C.P.Ed. in 1882, after which he entered the Navy, attaining the rank of fleet surgeon on February 26th, 1899. He served as surgeon of H.M.S. *Albacore* during the Sudan campaign in 1884-5, at Suakim, and received the Egyptian medal and the Khedive's bronze star. After retiring from the Navy, during the war of 1914-18 he served as a temporary major in the R.A.M.C., and afterwards as a deputy commissioner under the National Service Ministry.

Medico-Legal

DUTIES OF THE MEDICAL WITNESS.—IV

TECHNICAL LANGUAGE*

Sir John Collie warns the doctor to avoid any suggestion that he is speaking down to the intelligence of the court or that he considers the judge and jury ignorant of the matter in hand. Nevertheless, one of the hardest tasks of the medical witness is to explain the medical facts fully, in plain, non-technical language, without seeming to patronize the court. A doctor habitually thinks and speaks the language of his profession, and it is difficult for him suddenly to express himself on technical subjects in plain English—perhaps the more so if he is given to writing papers in the medical press. But he must try to put himself in the position of the persons to whom he is speaking, whose occupations are very different from his own and who perhaps just for this one hearing come into contact with an entirely strange language and habit of thought. Let him recollect his own feelings when he was last buttonholed by an enthusiastic constructor of wireless receivers or by a friend who had just started to learn to fly an aeroplane. The judge certainly, and counsel possibly, know a good deal more about medicine and its language than they care to give away. Their general attitude is to assume ignorance in order to keep the medical witness down to earth. This is obviously necessary if there is a jury, because the jury has to try the case as far as the facts are concerned, and the judge must be most careful to see that it is given every opportunity to understand those facts. He can best do this by assuming no more knowledge of medicine than the collective knowledge of the jury, which is certain to be scanty and erroneous. There cannot be any doctors on the jury. Moreover, technicalities are a convenient cloak for lack of precise knowledge. Not only should the witness be sure that he is not using them in this way, but he should be careful not to give anyone in court a reason to say, "I don't know what the man is talking about, and I don't believe he does either."

So the medical witness, in addition to his other troubles, must give his evidence in what for him amounts to a foreign language. Instead, for example, of saying, like the witness in "Taylor," that the victim was suffering from "a severe contusion of the integuments under the left orbit, with great extravasation of blood and ecchymosis in the surrounding cellular tissue, which was in a tumefied state; and also from considerable abrasion of the cuticle," he must simply say that the man had a black eye. On the other hand, he must on no account give the slightest sign of impatience with or contempt for a collection of persons whose intelligence is so low that they have never heard of a sacro-iliac joint and do not even know what is meant by a supracondylar fracture. He might not be happy himself if he were required to translate the expressions "0.5 per cent. lagging power factor," "lying four points off the wind under a single jib and close-reefed main," or "tenant in tail with possibility of issue extinct." He ought rather to convey an apology that doctors use a language which ordinary men cannot understand. If he has to use a strange word, he should follow it up with an explanation; for example: "pain in the left sacro-iliac joint, where the lower part of the backbone is attached to the haunchbone on the left side." He can always make himself much clearer if he can take the appropriate bones, a diagram, or a model into the box with him.

Just as the medical witness should prepare himself for cross-examination by argument with a medical friend, so he should prune his evidence of unconscious technicalities by trying it on a lay friend. He could probably not find a better critic than his wife, unless she is also medical, for lay women are even more impatient of technicalities than lay men.

THE WHOLE TRUTH

Finally, counsel for the witness's side will sit down and leave his witness to the tender mercies of cross-examining counsel for the other side. It sometimes happens, though not very often, that he has left untouched some point of evidence which the doctor thinks is essential to the proper understanding of the case by judge and jury. The doctor has then a right, if he thinks fit, to state to the judge that he has something important to say in order to satisfy his oath to tell the whole truth. He should not thus take the conduct of the case out of the hands of his own counsel unless as a conscientious but a sensible man he feels that he would not be playing his part properly if he kept silent. The instances in which he is justified in taking the initiative are rare. The judge will probably tell him to answer cross-examining counsel's questions first and then afterwards invite him to say what he wishes to—if he has not already told it to cross-examining counsel. It is perhaps fairer that the witness should give this unasked evidence in chief and not in cross-examination, so that his own counsel may know what he has to meet, and may by further examination put the most and not the least favourable complexion upon it.

CROSS-EXAMINATION

When cross-examining counsel gets up, the medical witness should brace himself for a contest, but not one between the two parties to the dispute. Counsel is fighting for his side; the witness for the truth as he sees it. Therefore, although he must of necessity treat counsel as an opponent, he must not for one moment, from first to last, regard him as an enemy. He must use the same courtesy, maintain the same helpful and constructive attitude, as he did when he was being examined in chief by counsel for his own side. He must treat cross-examining counsel in exactly the same manner as he treated the more friendly counsel who called him. The cross-examination may be a very severe test of his patience and dignity, but he must accept the ordeal and on no account allow himself to show irritation, even in the smallest degree. Counsel may try to make him lose his temper, and the witness must not let him succeed. As the learned editor of "Taylor" puts it, nothing can tend more to lower the witness in the opinion of the court or diminish the value of his evidence than the manifestation to deal with his examiner as if he were a personal enemy, to evade the questions, or to answer them with flippancy or anger. Such exhibitions invariably end in the discomfiture of the witness.

Of the two chief methods of cross-examination the bullying method, so well described in *Pickwick Papers*, has steadily lost favour, and has more and more given place to the alternative and subtler method known as "leading up the garden." Counsel is fully aware that a resolute witness can often be cajoled into indiscretions which the most savage attack would not force him to commit. Witness should therefore be even more on his guard against clever attempts to make him contradict himself and say what he does not mean than against attempts to make him angry. A favourite device of counsel is to repeat evidence that the witness has already given in chief, but in a slightly different form, just a little weaker or a little stronger than the witness actually gave it. If the witness accepts this variation, counsel will proceed to expand the apparently trifling verbal difference into a vital contradiction. The doctor should therefore be particularly careful not to accept as his own evidence anything but what he has actually said.

When the witness was being examined in chief he was probably encouraged to speak at some length, to give his evidence in his own way, and to make what explanations he chose. In cross-examination he will be expected to go to the opposite extreme, for counsel will ask him a series of leading questions and try to make him rest content with an answer of plain "Yes" or "No," which will nearly always leave him committed to some statement which is quite different from the evidence he means to give. Witness must resist this attempt. He has sworn to tell the whole truth; few medical questions can be truthfully

* The first of this series of five articles by a legal correspondent appeared on March 3rd (p. 407), the second on March 17th (p. 508), and the third on March 31st (p. 600).

answered by "Yes" or "No," and he has a right to qualify or amplify this answer. He should therefore give his "Yes" or "No," immediately followed by a short, precise explanation. Sir John Collie writes that that eminent expert witness Sir Frederick Bramwell, when pressed to answer "Yes" or "No," got out of the difficulty by answering "'Yes' and 'No,'" and adding, "Now I will explain what I mean by that." The explanation should be as brief and clear as possible, for a long, rambling one is apt to make the witness appear to be not quite candid.

The opponent's counsel is given a very free hand, and can practically ask what questions he likes. Nevertheless, the court recognizes certain limits. A judge can, for instance, disallow irrelevant and vexatious questions, such as questions the object of which is to make a witness admit that he did something improper a long time ago, or questions which are damaging without really affecting the witness's credibility, and the doctor may appeal to the judge if he considers that a given question comes into this class. The medical witness should bear in mind, however, that he is expected to stand on his own feet under cross-examination as in other unpleasant situations in life. He should, generally speaking, be as reluctant to appeal to the judge as he would be to appeal to the referee in a game of Rugby football. The judge will always intervene if the rules are really broken.

CONFLICT OF LOYALTIES

The medical witness's chief difficulty comes when he is asked a question which he cannot truthfully answer without offending against medical ethics. He is sometimes invited to criticize another medical man. If he is asked whether, upon the evidence he has already heard, he considers that another medical man has shown a lack of due care and skill, he need not answer the question (*Collier v. Simpson*), but this authority will not excuse him from giving such an opinion on facts observed by himself. His best attitude is complete frankness. If he has a good reason for not expressing an opinion on the work of another medical man—if, for example, the work is outside his own practice or knowledge—he should say so to the judge. If he is prepared to give a favourable opinion, well and good; but if a truthful answer means asserting that a brother medical man has, in his opinion, not exercised sufficient care or skill, he had far better not beat about the bush or make half-hearted attempts to "whitewash" his colleague: to do so will not help the other man and will discredit the witness. He should insist on keeping to concrete details, and not, if he can help it, be led into general expressions of criticism. In dealing with matters of care, he may well confine himself to a statement that he, in the other man's place, would have done so-and-so; on matters of skill he may not be able to avoid comparison with a hypothetical average standard. If the whole action turns on whether the doctor in question has behaved negligently, the witness can properly ask the judge to excuse him from answering the question which the jury is there to try.

(To be concluded)

A new edition of the *Official Guide Book of Medical Post-Graduate Work in Hungary* has just been issued by the Hungarian Medical Post-Graduate Committee (VIII, Máriáutca 39, Budapest). This excellently illustrated volume contains full details, in English, of the various hospitals and clinics where all kinds of medical post-graduate work can be undertaken. It is stated that all the professors and chief physicians speak English, French, or German. In addition to its main office in Budapest, the Post-Graduate Committee has subcommittees in the other university towns, and arrangements for study can be made wherever desired. Much modernization of the existing institutions has been effected in the last few years, and several new medical buildings have been erected. The *Guide Book* also contains information about places of historic interest in Hungary. There are now in that country four medical facilities, with 4,520 beds available for medical and post-graduate training, as well as 21,534 beds in the large public hospitals.

Obituary

STANLEY MELVILLE, M.D.

President, British Institute of Radiology; Formerly Radiologist to St. George's and the Brompton Hospitals

Dr. Stanley Melville's sudden death from heart trouble, on April 6th, came as a great shock to a wide circle of close friends, particularly among radiologists. A man endowed by nature with a genius for friendship, his loss is felt as keenly as any that his specialty has sustained for many years.

Melville was born in 1869, qualified L.S.A. in 1891 and M.R.C.S., L.R.C.P. in 1893, and obtained the degree of M.D. at the University of Brussels, with distinction, in 1899; he was also called to the Bar by Lincoln's Inn. As a pioneer in x-ray work he did as much as any other man to bring this, the youngest of the medical sciences,

into its rightful place as an invaluable aid to all the others. He gave up a flourishing general practice when the fate of radiology was so problematical that only men of great enthusiasm and courage dared to stake their career on it, and it is fitting that his devotion and labour should have been rewarded by his appointment to leadership and direction in practically every radiological movement of any importance. When, as the result of his efforts, and those of a number of his colleagues,

Cambridge University established its Diploma in Medical Radiology and Electrology, Stanley Melville was made an original member of the Diploma Committee; he frequently acted as examiner, and until his death took great interest in the diploma and in the training of candidates for it. One of the foundation members of the Röntgen Society, the forerunner of the British Institute of Radiology, he acted as its honorary secretary for many years, and was president this year. In conjunction with Professor Sidney Russ he was also honorary secretary of the X-Ray and Radium Protection Committee, which he was largely instrumental in founding. Melville joined the British Medical Association in 1923, and rendered valuable service as vice-president of the Section of Radiology at the Manchester Meeting in 1929 and as president of that Section at the Centenary Meeting in 1932. He was a member of the Consultants Board in 1932-3. His hospital appointments were too numerous to catalogue, but among the most important of his activities were: his post of honorary radiologist to St. George's Hospital, which he had to relinquish some years ago on account of failing health; his advisorship to the London County Council; his membership of the Radiological Committee of the British Red Cross Association, for which he and the late Dr. Robert Knox were to a large extent responsible; and his work at the Brompton Hospital for Diseases of the Chest. Dr. Melville made radiology of the chest his special study, and in his association for many years with the Brompton Hospital he, perhaps more than any other man, helped to bring this branch of radiology to its present state of perfection.

As a man, Melville possessed a very great charm. He had a warm, mellow personality, combined with a sincere and robust character; and while he was completely uncompromising and fearless in controversy, he remained a firm friend of those with whose opinions he differed most keenly. Two months before his death he suffered an

overwhelming blow in the loss, after a long and painful illness, of his wife, to whom he was devotedly attached. He elected, however, to remain at work, but his heart was not equal to the strain, and he died, as he would have wished to die, whilst still actively following his profession.

At the funeral service on April 10th Dr. F. D. Howitt represented the British Medical Association.

We are indebted to Sir HUMPHRY ROLLESTON for the following appreciation:

As Stanley Melville's former colleague at two hospitals in London, and as a friend from the time when, a general practitioner in Nevern Square, he began radiological work at Charing Cross Hospital with the late Dr. Ironside Bruce, may I emphasize the outstanding importance of his long-continued interest and active influence in connexion with the development of British radiology—the standards, education, and qualifications of those engaged in this branch of medicine, radiologists and radiographers. He was much concerned in the preliminaries which led to the establishment of the first diploma in this country for radiologists, that of Medical Radiology and Electrology (D.M.R.E.) at Cambridge in June, 1919, and was a constant and energetic member of the joint committee of teachers in London and Cambridge which is responsible for the instruction and examinations for the diploma. After the death from aplastic anaemia in 1921 of Ironside Bruce, he was the moving spirit in the formation of the X-Ray and Radium Protection Committee—the first in the world to issue recommendations to prevent the harmful results of irradiations. With Professor Sidney Russ he was honorary secretary of this committee since the start; its recommendations formed the basis of those which were adopted internationally in 1928 at the Stockholm congress. The eventual establishment in 1927 of the British Institute of Radiology incorporated with the Röntgen Society, after long-drawn-out negotiations, owed much to his persistent efforts to overcome difficulties, and he was deservedly the president at the time of his death. The amount of quiet and unobtrusive labour he devoted to these objects will probably never be known; but his friends recognized that he carried them out under the handicap of painful physical disabilities, of which those due to x rays were by no means the sole, and that in addition the long illness of his charming wife, which terminated fatally this year, had profoundly affected him.

ROBERT SEPHTON, M.R.C.S.

Atherton, Lancs

On Easter Monday, April 2nd, Dr. Robert Sephton died very suddenly at his home, the Manor House, Atherton, near Manchester. He was born on March 3rd, 1844, and was therefore in his ninety-first year. He retired from practice in 1920, but enjoyed remarkably good health almost to the end. He joined the British Medical Association in 1870, and had thus been a member for sixty-four years.

Robert Sephton began his medical career as an apprentice to a doctor in Liverpool and went to Atherton on October 1st, 1866, obtaining the M.R.C.S. in the following year. When he first started in general practice it was as assistant to his elder brother, the late Dr. Richard Sephton of Culcheth, near Warrington. This arrangement, however, was not of long duration, and the Atherton practice was soon made entirely independent. Dr. Sephton proved to be a most popular doctor in the district, and his practice became very extensive. His genial manner and happy disposition won the hearts of his patients, and, even after his retirement, he was always regarded by them

with sincere affection. He took a great interest in public life, serving continuously as a member of the Leigh Board of Guardians for the remarkable period of fifty-two years (1875–1927), during which period he was many times chairman. He was elected in 1895 to the Lancashire County Council, of which he became an alderman in 1913, holding that position until his death. He served on many committees of the Council, among which reference may be made to the fact that he was for some time chairman of the Public Health Committee of the county. He was also a member of the County Mental Hospitals Board and of the Midwives' Committee. In addition, he was a justice of the peace for the County of Lancaster for twenty-seven years. The record of his public service is much too long for this brief statement, and must be almost unique. Dr. Sephton was interested in the industries of Lancashire, more especially in cotton-spinning and in the manufacture of nuts and bolts. He was, further, a prominent Freemason, being a member of the West Lancs Provincial Grand Lodge. Few men have won more universal regard and esteem. Public life always involves criticism, but those who most strongly disagreed with the policy followed by Dr. Sephton were always ready to acknowledge his absolute honesty and his unfailing justice. He was never ruffled, and his good humour and kindness of heart made him a man who will be very greatly missed.

Dr. Sephton married in 1872 Eliza, daughter of the late Ralph Poole of Atherton; his wife died five years ago. He leaves two sons and three daughters, his elder son being medical superintendent of the County Mental Hospital at Lancaster, while his younger son is the deputy chief engineer of the G.I.P. Railway in Bombay.

G. ARTHUR CARDEW, O.B.E., M.R.C.S.

Cheltenham

By the death of Mr. George Arthur Cardew on March 29th, aged 77, Cheltenham has lost one of its outstanding citizens, the profession one of its ablest and most valuable members, and the writer of this notice a friend of nigh fifty years' standing.

He was educated at University College, London, and Queen's College, Birmingham, and qualified M.R.C.S. and L.S.A. in 1877. In 1879 he became house-surgeon to the Cheltenham General Hospital, succeeding the famous Dr. David Hartley, who for forty years had occupied the post. Mr. Cardew's zeal and his efforts to bring the hospital up to date by instituting modern methods of treatment brought him a certain amount of opposition. With persistence and tact he soon, however, overcame this. In 1881 he vacated this appointment to take up private practice in the town. Soon afterwards he became the energetic honorary secretary of the Gloucestershire Branch of the British Medical Association, and later on its president. He then joined Mr. L. Winterbotham, an honorary surgeon to the hospital and a member of that well-known Gloucestershire family. Able, honest, and sincere, Mr. Cardew inspired confidence, and he soon built up an extensive and first-class practice. To those who did not know him he might perhaps seem a little brusque, but when you got to know him he was a loyal and kind friend. In 1910, when the council of the Ladies' College appointed a medical staff, he and I, who were already medical attendants at the college boarding-houses, were among the first members. We were also trustees of the Delancey Fever Hospital, both before and after it passed into the hands of the Cheltenham Corporation. Both these appointments he held until his last illness. A recital of the various other appointments and positions he held is simply a record of his wonderful activities and the diversity of his interests.

Mr. Cardew was for many years an officer of the Gloucestershire Royal Engineer Volunteers, and in 1903 he became lieutenant-colonel in command of the battalion. He held this rank until the battalion was disbanded under the Territorial Army scheme. Afterwards he became president of the G.R.E.V. Union. He was one of the first lecturers for the St. John Ambulance in Cheltenham. Shortly after the Great War broke out he took charge of the St. John Hospital at the Gloucester Road Schools. His splendid services there were recognized by the bestowal of the O.B.E., and he was also made an esquire of the Order of St. John of Jerusalem. He held the Volunteer Decoration and also the Diamond Jubilee Medal. In recent years he was chairman of the Cheltenham District Nursing Association (Victoria Home). When the British Medical Association met at Cheltenham in 1901 he acted as joint local secretary of the meeting. Mr. Cardew was a keen student of archaeology, had written many articles on the subject, and possessed a fine collection of flints. It was always a mystery to me how, with such an extensive practice, he could find time for all this outside work.

The death of his younger son, a lieutenant in the Royal Navy, in 1917 after a long and painful illness, and the death of his dear wife in 1930, affected him deeply, and he was never quite the same man afterwards. I was privileged to be near him in these times of trouble and sorrow, and I shall never forget his courage, fortitude, and resignation. The family—father, mother, two sons, and daughter—was an ideal one, so united, kind, and considerate to each other. It was therefore comforting and fitting that in the sunset of his life he had the tender care of a devoted daughter. His passing has left a deep sense of personal loss in the hearts of many.

R. K.

Dr. GEORGE ROBERT SEAGER THOMAS, who died suddenly at his home in Southampton on March 31st at the age of 46, was a well-known pathologist and police surgeon. He received his medical education at Cambridge and the Westminster Hospital, obtaining the diplomas M.R.C.S., L.R.C.P. in 1914, and graduating M.B., B.Ch. in the following year. His first appointments were resident surgical officer in the military wards at the Westminster Hospital, medical officer in charge of the children's out-patient department and superintendent of the pathological department at that institution, and bacteriologist to the City of Westminster. He was also for a time pathologist to the Norfolk War Hospital, and to the Royal Victoria Hospital at Netley. In addition to being senior police surgeon at Southampton, Dr. Seager Thomas was, at the time of his death, honorary pathologist to the Royal South Hants and Southampton Hospital, and the children's and ophthalmic hospitals in that town; consulting physician to the Hythe Memorial Hospital; and pathological specialist for the South-East region of the Ministry of Pensions. He performed the necropsies and gave expert evidence in a number of murder cases, including the Southampton garage murder in 1929. He frequently worked in co-operation with Sir Bernard Spilsbury, and at the time of his death was assisting him in the pathological investigation of the death of Mrs. White, in her bungalow at Hordle. He was to have been a witness at the adjourned inquest next month. One of his chief hobbies was botany, and he spent much of his spare time in the New Forest searching for rare specimens.

By the sudden death, on March 26th, of Dr. R. D. MACKINTOSH the borough of Barnes has lost a physician who was greatly loved. Robert Dunbar Mackintosh, who was born in 1865, came of old Highland stock, but his parents migrated to Ayrshire during his childhood. He was educated at Ayr Academy and Glasgow University, where he graduated M.B., C.M. in 1888. Shortly afterwards he succeeded his brother in the practice of Dr. William Marshall of Barnes. "Dr. Mac," as he was

affectionately known in Barnes, was a patient and skilful practitioner, and his ability would have become more widely recognized but for an accident which befell him at the height of his powers: a severe infection, caught from a patient, nearly cost him his life, and permanently affected his hearing. He was unfailingly generous: it was said that "he never charged a fee without first having a peep into the larder," and he had a genius for friendship with the young. He was a notable benefactor of local charities; hardly a year passed but one of his plays was performed in a good cause, and his pageant, *Queen Bess in Barnes*, was produced in many parts of the district. Dr. Mackintosh never forgot his Highland origin; he was a keen student of Gaelic and of Scottish history and romance.

The Right Rev. JOHN EDWARD HINE, D.D., D.C.L., M.D., Assistant Bishop of Lincoln since 1930, who died on April 9th on the eve of his seventy-seventh birthday, studied medicine at University College Hospital, and qualified M.R.C.S. in 1879. He then held for two years the post of resident medical officer at the Radcliffe Infirmary, Oxford, graduating M.D. Lond. in 1883. In 1886 he was ordained, and, after two years as curate at Richmond, Surrey, went out, under the Universities Mission to Central Africa, to Likoma, of which he was consecrated bishop in 1896. Five years later he was translated to Zanzibar, and from 1909 to 1914 was first Bishop of Northern Rhodesia. Bishop Hine told the story of his life in a book published ten years ago under the title *Days Gone By*.

We regret to announce the death, from pneumonia, in his twenty-eighth year, of Dr. VICTOR T. PARKINSON on April 1st, at the Leasowe Open-Air Hospital for Children. In December, 1930, he graduated M.B., Ch.B. at the University of Liverpool, and, after serving at the Royal Infirmary and Mill Road Infirmary as house-surgeon and resident medical officer, he took up the position of assistant medical officer at Leasowe. A short time later, when the senior medical officer resigned, he was appointed to take charge of the hospital. Up to the time of his death he had thrown himself into the work and devoted himself to increasing the scope of the hospital while maintaining its high standard. "P. H. W." writes: Parkinson was a keen worker, and his flair for administration made him the ideal man for the position he held. He was loved by all the children and the staff, and was very popular with his colleagues and those with whom his work threw him into contact in the surrounding counties. He was a keen golfer, and was always popular in whatever circles he found himself. His untimely death has left an irreparable gap in the medical work which he so faithfully carried out.

The Federated Malay States Division of the British Medical Association suffered a severe loss by the death, in a motoring accident on November 26th, 1933, of Dr. M. Y. LUM, at the early age of 40. Dr. Lum, who was born in Canton, received his general education at the Methodist Boys' School, Kuala Lumpur. He took his medical degree at Hong-Kong, where he had proved himself a distinguished student. Returning to Malaya, he entered the Malayan Government service, and three years later started in private practice. For many years he devoted considerable time to the executive, scientific, and social work of the British Medical Association in Malaya, and at the time of his death was chairman of the Division. He took a keen interest in the Chinese Maternity Hospital in Kuala Lumpur, where his work and influence will be greatly missed. His untimely death has left a gap which will be difficult to fill.

The following well-known foreign medical men have recently died: Professor RODOLEO STANZIALE, director of the dermo-syphilitic clinic of Naples University; Dr. JACQUES LE GRAND, professor at the medical school at Rouen and surgeon to the Rouen hospitals; Dr. ALEXIS

VICTOR MOSCHCOWITZ, formerly professor of clinical surgery at Columbia College, New York, aged 68; Dr. J. M. TROYA, one of the pioneers of ophthalmology in Ecuador; Professor CARL BRUHNS, director of the dermatological clinic at Berlin-Charlottenburg, who took an active part in the campaign against venereal diseases, aged 65; Dr. FRITZ HABER, professor at the Kaiser Wilhelm Institute at Berlin-Dahlem, and winner of the Nobel prize for chemistry in 1919; Dr. ALFREDO LARGUIA, an eminent paediatrist of Buenos Aires; and Dr. L. PIERCE CLARK, a New York authority on epilepsy.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons resumed on April 9th, and the House of Lords on April 11th. In the Commons the Road Traffic Bill was read a second time, and a Water Shortage Bill introduced. Debate arose on slums. The discussion on the resolution allotting money to aid the production of pure milk and for other purposes was postponed because of the illness of Dr. Elliot, Minister of Agriculture.

Corrigendum

We regret that the paragraph in last week's issue (p. 649) giving the Minister of Health's reply concerning the outbreak of small-pox at Blackburn was incorrectly headed "Small-pox Outbreak at Nottingham."—ED. B.M.J.

Dinitrophenols

Captain Erskine Bolst gave notice that on April 12th he would ask the Home Secretary what time would elapse before action was taken to place on the appropriate poisons schedule dinitrophenols and dinitrocresols, drugs the use of which for "slimming" purposes had proved fatal in several recent instances.

The Government's Housing Policy

On April 9th, during a debate on the Civil Estimates, Mr. Hicks called attention to the administration of the Ministry of Health, in relation to housing. Sir HILTON YOUNG expressed the hope that the House, the local authorities responsible for housing, and public opinion as a whole would follow from month to month and year to year, during the five-years' programme of the Government, the actual achievements of the housing authorities to make sure that the programmes were carried out in time to achieve what the Government believed to be possible within the five years. It should be realized, he continued, that we were still in the period of acceleration in regard to pulling down the slums and putting further houses in their place. We had, however, already increased the speed of the work sufficiently to assure us that, if it was continued, we should complete the programme in five years. The actual acceleration of slum clearance was best shown by the figures of the resolutions declaring clearance areas. That was a critical point—the point at which the slum was actually declared to be a slum, and its clearance and the provision of fresh housing accommodation were made inevitable and certain. In the year which began on January 1st, 1933, 200 local authorities declared 894 fresh areas. In the three months from January 1st of the present year to the end of March the number of fresh areas had been nearly 1,000. Therefore, in the last three months more areas had been declared than in the whole of the preceding year, and we had already multiplied the rate of progress in slum clearance by four in the carrying out of the programmes. The curve was going up, because some of the biggest figures we had ever had were those for last March, when 347 fresh areas were declared. He hoped it would be possible to shorten the time which it took to get the schemes through, and, with experience of the working of the Act, he believed that the local authorities would be able so to organize their machinery as substantially to accelerate the progress of the work. In the six months to the end of last September between 55,000 and 66,000 small houses for the lower-paid wage-earners were built by local authorities and private enterprise combined. That compared quite favourably with

previous years, and it was encouraging to observe that this activity continued, to the best available information, undiminished. The lesson experience taught was that an uncontrolled subsidy was useless to cure the housing difficulty. That was the basis of the Government's policy, and it was being developed stage by stage. The second foundation stone of the Government's policy was that, with the assistance of public funds, backed by the whole housing energy and public opinion of the country, the slums should be no more. When that organization was completed and the attack launched on the slum evil, the Government could go on to deal with overcrowding. That was a matter which, when the time was ripe, as it would be before long, he would develop to the House.

Water Supplies: Emergency Measures

Mr. ATTLEE asked the Prime Minister what was the present position with regard to water supplies in the country, and what measures were proposed to meet the conditions arising out of the drought. Mr. MACDONALD said that the reserves of many water undertakings had fallen to a low level for this time of the year. The Government had been carefully watching the situation and, because of the continued absence of abundant rains, was satisfied that emergency measures must be taken. The Government therefore proposed to bring legislation before the House immediately. The Minister of Health would present a Bill on the following day. The second reading would be taken on April 12th instead of the Milk (Money) Resolution and other business announced for that day. Replying further to Mr. Attlee, Mr. MacDonald said that the Rural Water Supplies Act, which Parliament had just passed, was sufficient for its purpose, but the situation had worsened since, and required measures of a different character.

Sir HILTON YOUNG introduced the Bill on April 10th, under the title of the Water Supplies (Exceptional Shortage Orders) Bill. It applies to England, Wales, and Scotland, and is to be valid until the end of 1935. It will authorize the Minister, on or without a prior local request, to make orders for the supply of water from one undertaking to another, the development of new sources, the entry on land for this purpose, the pooling or rationing of supplies, and the reduction or withdrawal of "compensation" water. The Ministry of Health is advised that the March rains did practically no good in replenishing supplies; the summer rains will add little, and the effect of the drought on underground sources will not be manifest for some time. The normal expectation of rain is no longer sufficient to put supplies right, and the Bill is designed to put the remaining supplies to the best use. A special belt of drought is reported from North Wales, through parts of Lancashire and the West Riding, and many of the Pennine supplies are much depleted. Shortage is also reported in the Midlands, as at Kettering, and, apart from the provisions of the Bill, appeal is made for general economy by water undertakers and consumers. The recently passed Rural Water Supplies Act will remain operative, but the objects of the Supply of Water in Bulk Bill will, during the emergency, be more quickly achieved under the new Bill.

Medical News

Sir George Newman will deliver four lectures on "The Special Hospital Services" at Gresham College, Basinghall Street, E.C., on April 17th, 18th, 19th, and 20th, at 6 p.m. The lectures will be illustrated by lantern slides. Admission free.

The St. Cyres Lecture for 1934, on "Cardiac Arrhythmias," will be delivered at the National Hospital for Diseases of the Heart, Westmoreland Street, W., by Dr. J. M. H. Campbell on Wednesday, May 9th, at 5 p.m. Members of the medical profession are invited.

At the next meeting of the Chelsea Clinical Society, to be held at the Hotel Rembrandt, Thurloe Place, S.W., on Tuesday, April 17th, at 8.30 p.m., Mr. E. G. Boulenger will give an address on "Behind the Scenes at the Zoo Aquarium" (with lantern slides). The meeting will be preceded by dinner at 7.30 p.m.

The Queen will open the new wing (comprising the new Radiological Department in Granard House) of the Cancer Hospital, Fulham Road, S.W., on Wednesday, May 9th, at 3.30 p.m.

A meeting of the Medico-Legal Society will be held at 11, Chandos Street, W., on Thursday, April 26th, at 8.30 p.m., when a paper will be read by Mr. Claud Mullins, metropolitan police magistrate, on "How should Sexual Offenders be dealt with?" which will be followed by a discussion.

The sixty-first annual public meeting of the National Temperance Hospital, Hampstead Road, N.W., will be held in the out-patient hall on Wednesday, April 18th, at 4.30 p.m., with the president, Sir H. Percy Shepherd, in the chair.

A meeting of the Royal Microscopical Society will be held at B.M.A. House, Tavistock Square, W.C., on Wednesday, April 18th, at 5.30 p.m., when papers will be read by Mr. F. Haynes and Mr. B. K. Johnson.

A post-graduate course on diseases of children will be held at the Hospital for Sick Children, Great Ormond Street, W.C., from April 30th to May 12th, from 10 a.m. to 1 p.m. and from 2 p.m. to 4 p.m. daily, except Saturdays (10 a.m. to 1 p.m.). The course will consist of fifty clinical lectures and demonstrations and six laboratory demonstrations; the fee is £6 6s.

The Fellowship of Medicine announces lecture-demonstrations by Dr. Clark-Kennedy at 11, Chandos Street, on April 17th on "Murmurs," and on April 24th on "Cardiac Irregularity." Dr. Ellman will lecture on "Pleural Effusions" on April 18th, and on "Intra-thoracic New Growths" on April 20th, both at 8.30 p.m. Dr. Edridge-Green will lecture at 4 p.m. on April 19th on "Vision and Colour Vision." A week-end course in gynaecology will be given at the Samaritan Hospital for Women on April 28th and 29th. Other forthcoming courses include psychological medicine, at the Maudsley Hospital, April 23rd to June 1st; dermatology, at St. John's Hospital, April 30th to June 2nd (afternoons and evenings); a week-end course in medicine and surgery, at St. Mary's Hospital, Plaistow, all day, June 2nd and 3rd. Inquiries should be addressed to the secretary of the Fellowship, 1, Wimpole Street, W.1.

The following German congresses will be held in May: Society of Oto-Rhino-Laryngologists, May 17th to 19th at Würzburg; Pathological Society, May 22nd at Rostock; Society for Psychiatry, May 23rd to 26th at Tübingen; Society for Welfare of Cripples, May 25th to 26th at Berlin.

The first Spanish Congress of Health will be held from May 6th to 12th, when the following subjects, among others, will be discussed: the organization of the services of rural hygiene, infantile hygiene, the campaign against tuberculosis, and centres for research and education in hygiene. The subscription is 50 pesetas. Further information can be obtained from the general secretary, Dr. L. N. Angulo, Dirección General de Sanidad, Plaza de España, Madrid.

The second French Congress of Phoniatriy will be held in Paris on May 12th, under the presidency of Professor Moure, when Dr. Labarraque will read a paper on rhinological operations and phoniatriy. Further information can be obtained from the general secretary, Dr. Tarneaud, 27, Avenue de la Grande Armée, Paris, 16e.

The Minister of Health has been informed by the Treasury that by a further agreement of the National Whitley Council for the administrative and legal departments of the Civil Service the arrangements for stabilization of Civil Service remuneration embodied in the memorandum of August 15th, 1932, will continue to apply on and from April 1st, 1934, pending the conclusion of negotiations for their replacement. The effect of this decision is to extend for a further period the operation of the Minister's circular letter of March 7th, 1932.

A medical tour is being organized for Whitsuntide to four of the Rhineland spas, including Bad Nauheim and Wiesbaden. Particulars may be had from the London representative and organizing secretary, Mr. Robert O. Rohme, 90, Sheaveshill Avenue, N.W.9.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Ailology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Medusecra Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

"A Terrifying Yell"

"J. F." (Manchester) writes: I have under my care a girl, aged 12½ years (first menstruation at 12 years), who for seven weeks past has been emitting a terrifying yell at intervals of five minutes for twelve hours daily. The "yell," which lasts on an average for six seconds, is accompanied by an extreme extrusion of the tongue. She has no warning of its onset, and becomes normal almost immediately it has passed off. The "yell" can be heard in the street at a distance of thirty yards, even when the bedroom window is closed. Fortunately, up to the present, it does not occur at night time. The nearest approach to a description of the yell is what I could imagine would be the "last terrifying shriek of someone being murdered." No treatment so far has been of any use. Can anyone help with a suggestion as to either diagnosis or treatment?

"Bee Wine"

Dr. C. T. Roe (Lincoln) writes in reply to "Ferment" (April 7th, p. 652): "Bee wine" is a fermentation of sugar and water by means of *Saccharomyces pyriformis* and *B. vermyforme*. The ferment is sold dry by chemists; when active it looks like "bees" floating in liquid. The mixture is usually placed on the mantelpiece to ferment.

Dr. R. CRAIK (West Ealing) sends fuller information. "Bee wine," he writes, is a name given to cane-sugar solutions fermented by a bottom yeast, of which, during fermentation, small lumps keep rising to the surface like bees in flight. The classical example is Old English ginger-beer, the fermentation of which was proved, by the late Professor Marshall Ward, to be due to the symbiosis of a yeast (*Sac. pyriformis*) and a bacterium (*B. vermyforme*). Lafar (*Technical Mycology*, vol. ii, p. 280) gives a description. I am told that working samples are often on sale in London during the summer at the Caledonian Market. The different names—"Californian bees" and "Macedonian bees"—suggest that the English ginger-beer plant has no monopoly of the process. And I have a yeast, recovered from spum, which gives an active dancing fermentation in cane-sugar solutions—otherwise it resembles fruit yeasts of the *Sac. marianus* type.

Income Tax

Pay during Leave—Special Study

"H. R." maintains a house in England, and was here on leave during 1932-3. He "took a course of study for four months, and during that period was granted an allowance of 12s. a day . . . to cover the cost of the course." The expenditure actually incurred amounted roughly to about 7s. a day. Can he claim that as a deduction?

* On the assumption that the allowance of 12s. a day was given on condition that the course of study was undertaken, and would not otherwise have been received, we are of the opinion that "H. R." can claim to deduct the

expenditure as incurred as outlay to enable him to obtain the allowance.

Cost of Visiting Hospitals

"F. G." writes to say that he has been refused—after appeal to the Commissioners—the deduction of the expense of travelling from the town in which he practises to London, where he holds an appointment as senior clinical assistant.

** Legally that is correct. There is, however, a general practice which has long official sanction of pooling appointment receipts with those of the general practice, and allowing the whole of the gross expenses against the aggregate gross receipts. But the normal case is one where the appointment is a local one. In the present instance there is a distance of seventy to eighty miles between the residence and the place where the work of the appointment is carried on, and the Revenue authorities may very well regard that as outside the usual arrangement, and follow the strict legal course of making separate assessments. In that case our correspondent appears to have no remedy.

LETTERS, NOTES, ETC.

Aetiology of Silicosis

Lieut.-Colonel G. FOWLER, I.M.S. (ret.), writes from Ghatsila with reference to the report on silicosis and tuberculosis in South Africa (*Journal*, January 20th): An excellent article has been written on the causation of silicosis by Dr. W. K. Jones, in the *Bulletin of the Institution of Mining and Metallurgy* (published at 225, City Road, E.C.), and any of your readers interested in this disease should read it. It clearly shows that the disease is due to the presence of sericite (a hydrous silicate of aluminium and potassium) in a fibrous or acicular condition. The comparison between the South African gold mines and the Kolar gold mines in India is interesting, as in the Indian mines the dry method of drilling is still carried on, and yet the disease there is extremely rare, whereas with wet drilling in the South African mines silicosis still exists and is a menace to the workers. [See page 676.]

Ether Convulsions

Dr. MARGARET H. ELLIOTT (Belfast) writes: I have seen several occurrences of ether convulsions such as described by Dr. D. Masters Brown (*Journal*, March 31st, p. 579). They appear to occur when the patient is lightly anaesthetized, and sometimes a pre-existing toxic condition exists. When toxicity is present the patient seems, during the administration, suddenly to pass from the first stage of anaesthesia to what is apparently the third stage, but what is more probably a state of anaesthetic shock, apart from operative intervention, and which on these occasions does not encourage one to deepen the anaesthesia (as one would if operation was in progress), although hardly enough anaesthetic has been administered as would ordinarily produce the third stage of anaesthesia.

Professional Telephone Facilities

CETEX LTD. (19, Grosvenor Place, S.W.1), an organization operating an auxiliary exchange under licence from H.M. Postmaster-General, announces the extension of this service to medical men living in the London area. The system, which is already used by commercial concerns, offices, private individuals, and one London newspaper, offers a day-and-night service to each subscriber. There are two types of service—automatic and non-automatic. The former obtains within a radius of roughly a mile from Hyde Park Corner, the latter extends over the whole London area. With the automatic service a switch is fixed to the subscriber's telephone, so that if he has to leave his instrument unattended, all in-coming calls can be diverted on a special line to the Cetex exchange. These calls are answered by operators in that exchange who, using the formula "Mr. —'s secretary speaking," will take messages, fix appointments, advise as to the whereabouts of the doctor in question, and, following instructions previously given to them, get in touch with him if required. When the doctor returns to his consulting room it is only necessary for him to switch back the telephone, ring the Cetex exchange, and take whatever messages there may be waiting for him. This automatic service costs £52 annually, and includes line rental, engineering charges, maintenance costs, etc. Facilities in respect of the subscriber's home telephone number are included under this charge, so that he need not notify any numbers other than that of his home and his consulting room. For those who live outside the "automatic" area the non-automatic service can be arranged for ten guineas a year. By this system the doctor

gives as an alternative number that of the Cetex exchange. In the event of no answer being obtainable at his own house the caller rings up the alternative number, and messages, etc., are taken as in the case of the automatic service. Here, of course, it is necessary to notify on the stationery and in the telephone directory that the alternative number (Sloane 4554) must be rung if "no reply" is obtainable from the first number. It is pointed out that all messages, etc., are treated in strict confidence, and that each subscriber has a private code number.

The Meaning of "Vegetarian"

The secretary of the London Vegetarian Society (8, John Street, W.C.2) writes: The text of Dr. Robert Hutchison's Hastings Popular Lecture, as published in the *British Medical Journal* of March 10th, contains no reference to vegetarianism, as such, nor is the word "vegetarian" once included. The fact, however, that leading representatives of the lay press, in publishing their reports of the lecture, assumed that vegetarianism, as invariably defined in this country by those who practise it—that is, as implying abstinence from "fish, flesh, and fowl"—had actually been disparaged, seems to call for some comment. "Doctor critic of vegetarianism," says one; "It is difficult to secure good nutrition by vegetarianism"—on the supposed authority of Dr. Hutchison—declares another. It seems plain, however, that at some point in the lecture the word "vegetarian," in one or other of its forms, was inadvertently used to denote the practice (so far as such, in this country, may be said to exist at all) of living entirely on the produce of the vegetable kingdom, but the fact, Sir, that the word, bearing such erroneous implication, did not actually appear in your own pages, is, in itself, significant. Whether or not the choice of terminology in the first instance was a wise one is now beside the mark; clearly, the word is now well understood, and, also, it has come to stay. The current meaning—denoting, that is to say, abstinence from flesh foods, with or without the use of dairy produce—as adopted by all the vegetarian societies in this country, has been in force at least as far back as 1847, and its employment with quite a different connotation by the lecturer on the occasion above-mentioned seems singularly unfortunate. Moreover, etymologically, the position would seem to be quite clear, the derivation being from the Latin *vegetus*, which means "strong," "vigorous." If, by courteous publication of the present letter, you should see your way to help in clarifying what is to many a not unimportant issue, a good many of your readers, I feel sure, would be duly grateful.

"Periodical Sterility"

Dr. MARIE C. STORES (London, W.1) writes: In the letter under the heading "Ovulation and Menstruation," in the *British Medical Journal* of March 31st, Dr. Denzaburo Kato mentions, as though it were an established fact, that "periodical sterility was a great relief to those people who are not allowed to use any mechanical or chemical contraceptive methods, and who want to limit their families"—in short, what has long been popularly called "the use of the 'safe period.'" May I state the results of an extensive experience at a birth control clinic, and of confidences from every country in the world from people of all classes, that the so-called "safe period," far from being a relief, is a snare and a delusion, and I am much surprised that it should be spoken of in your *Journal* as though it were an established fact.

Limits of Cosmetic Medicine

A correspondent sends us the following extract from a London evening newspaper of April 6th. "Miss Bankhead has just had five months in hospital. She is the same Tallulah. The same husky voice. The same dark eyes and the same pallid complexion." Is this to be regarded as a failure on the part of American laryngologists, ophthalmologists, and dermatologists?

The Marmite Food Extract Co. Ltd. (Walsingham House, Seething Lane, E.C.3) has recently issued a pamphlet on the medical uses of marmite. According to a recent estimation one ounce of this product contains 840 international units of vitamin B₁.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 50, 51, 52, 53, 56, and 57 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 54 and 55. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 160.

ON THE CONTROL OF OBESITY*

BY

A. H. DOUTHWAITE, M.D., F.R.C.P.
ASSISTANT PHYSICIAN, GUY'S HOSPITAL

Sixty million pounds are spent annually in the beauty parlours of London. A considerable proportion of this sum is devoted to preventing the development of obesity or to combating an unsightly rotundity which has crept insidiously upon its victim. Yet this aim can be achieved with certainty without expense—in fact, with the exercise of economy. Two widespread fallacies in treatment should be at once exposed. The first is the wholesale exhibition of thyroid extract even though the gland be functioning perfectly. The other is the prescription of strenuous exercise to individuals already exhausted by the task of carrying about several stone of surplus fat.

DANGERS OF OBESITY

The obvious danger to a fat-laden body of microbial infection, or major operation, is too well known to need emphasis. On the other hand, the association of rotundity with many minor disabilities is less widely recognized. For instance, an extraordinary degree of impairment of muscular efficiency and signs indicative of cardiac embarrassment can be found in many people whose increase of weight at first glance appears to be trivial. All who have conducted post-mortem examinations will testify to the deplorable condition of the heart in the fat person. Not only are the usual pericardial deposits increased a hundredfold, but we find fat penetrating and destroying the myocardium relentlessly. The resulting impairment of the heart's action is almost always accompanied by deficient diaphragmatic movement, which is itself induced by the masses of omental fat which bulge the abdominal wall. No doubt it is a combination of these factors which is responsible for the high incidence of bronchitis and the invariable basal catarrh in the fat middle-aged individual.

The effect of fatness on mental processes is an interesting one. The old dictum of "Laugh and grow fat" should not be taken too seriously. In fact, it is questionable whether the cart has not been put before the horse. The fat person, as a rule, avoids effort, mental and physical, his critical faculties are dulled, and a tendency to laugh rather than to grumble shows his bias towards taking the easier path. This is why women urge their husbands to overeat. They exhibit the same attitude with regard to smoking. The affectionate term "fatty" conjures up a picture of the beaming subject of practical jokes. Yet, from time to time the habitual unruffled serenity of the obese is violently disturbed by an outburst of rage not infrequently occasioned by some quite trivial slight. Few persons realize what they are losing in respect of alertness by being fat until they take measures to restore their normal girth. It is during recovery that these patients exclaim with delight at the return of energy, interest in life, and the sensation of youth which accompanies it.

Loss of sexual attraction is an important consideration in keeping the population from obesity, but it is a feature which has not always been operative. At certain times in the world's history and in certain countries, extreme obesity in women has been regarded as attractive. Conversely, until recent years we have seen the younger females abolishing so far as possible every typical feminine curve. The explanation of this remarkable state of affairs is to be found in the increase of frankly or potentially

homosexual males, who arose from a childhood spent during the war, when they were subjected purely to feminine influence. We see now how cause and effect are on the wane.

The effect of obesity on fertility is more worthy of study. I have several patients whom I have assisted in normal outline whose temporary delight was marred by unexpected pregnancy. These women, having had one or two children, had become very fat and had gradually discarded contraceptive practice on the assumption that they could no longer bear children. The reduction of weight by dieting alone has restored fertility. In the male, impotence is more prone to arise.

Infiltration of the abdominal and perineal muscles with fat is responsible for the constipation and, in women, moderate incontinence of urine. The latter, in its turn, aggravates the existing intertrigo inherent in the flexures of every fat person. The bad stance induced by a pendulous abdomen commonly results in osteo-arthritis of the spine. The mere effect of excess weight and interference with the vascular supply of the joints by deposits of fat will induce osteo-arthritis of the knees in many cases. The alterations of the metabolism in the obese are still but imperfectly understood. It is certainly a fact that in the majority the basal metabolic rate is found to be normal, or even raised, provided the calculations take into account the increased body surface arising from the dead weight of fat in which metabolic processes are, to all intents and purposes, absent. A subnormal temperature is very common, and is quite compatible with a raised basal metabolic rate. From time to time outbursts of fever relieve the monotony as an expression of a spasmodic attempt on the part of the organism to destroy the material which is threatening its existence. Dyspepsia of a peculiar kind is to be observed in most of the gross obesities. It is characterized by a spurious appetite, by which I mean an inordinate desire to eat large quantities of food in an attempt to alleviate a sinking feeling in the epigastrium. As the meal progresses this sensation is overcome by drowsiness, and the victim is usually to be found snoring through a very liberal "forty winks" in the afternoon. If, added to all this, we recall the unpleasant body odour of the fat person, we need no more to convince us that obesity, if avoidable, is disgusting.

CAUSES OF OBESITY

It may be accepted as an axiom that fatness is due to excessive eating or to endocrine deficiency. Gluttony may, of course, be relative—that is to say, food intake has to be considered in relation to energy output. This is too obvious to need further stress. The excuses for over-indulgence are many and ingenious. The commonest is a denial that it exists. Nearly all fat people say they are small eaters, and often they are right. What they fail to recognize is that bulk and calorie value do not run parallel. It is worth while taking down from the patient's description a note of a day's food and analysing its energy equivalent. To find 500 calories in excess of requirements is quite common.

The necessity of keeping up strength, the sinking feeling without a meal, sleeplessness, or the remarks of neighbours that the patient is looking so ill—all or any of these may be used as an excuse for overfeeding. The most difficult of these arguments to overcome is that of sleeplessness.

*Address to the East Sussex Medical-Chirurgical Society, February 20th, 1934.

Prompted by posters of alluring beauties asleep with the aid of a hot drink of considerable food value, our patient, already disturbed by the indigestion of obesity, flies to the remedy and finds that it works—for a time. The sleep is induced, no doubt, by the diversion of blood to the splanchnic area, but in three hours the victim is wide awake again. What does she do? Reaches out for her thermos flask of hot milk, and so adds more fat to her greasy deposits.

Malt liquors are well known for their fattening properties, which are only slightly related to the trivial alcohol content. On the other hand, the avoidance of alcohol and smoking often drives the excessively righteously to an orgy of feeding which is more revolting than any vice he may have abandoned.

to function through glandular insufficiency. As an example, the photographs of a case of Frölich's syndrome are instructive.

This boy is aged 14, measures 5 ft. 10 in., and weighed 13½ stone. The feminine distribution of fat is well seen on the buttocks and flanks. The distribution of pubic hair and tendency to knock-knee is likewise characteristic. The remarkable height of the boy is due to the disproportionate development of the lower limbs—namely, 38½ in. as compared with 31½ in. from pubes to the crown of the head. This feature is the result of testicular insufficiency secondary to pituitary failure. Note the typical venous stasis in the lower limbs. To give such a boy thyroid would be futile. The absence of thyroid involvement is always clearly shown by the normal shape of hands, fingers, and toes, the healthy condition of the hair, and the facies. Actually this purely glandular

FIG. 3.

FIG. 4.

March 2nd, 1934. Note change in facial expression.

As to endocrine complicity in the development of obesity, my experience has been that this is present in some 20 per cent. of cases in clearly recognizable form. In a series of ninety-four cases seen privately, endocrine deficiency was present in eighteen, and of these there were ten examples of hypopituitarism, five of myxoedema, and three of gonadal insufficiency (two post-operative). Of twenty-eight hospital cases there were two examples of myxoedema, four of hypopituitarism (Frölich's syndrome), and the remainder were alimentary in origin.

It is particularly instructive to note that thyroid deficiency was unquestionably responsible for only seven out of 122 cases of obesity in view of the widespread and mistaken habit of prescribing thyroid extract to all fat patients. I quite realize that many of the other cases which I have classed as "alimentary obesity" had also some evidence of hypothyroidism, particularly those women whose pre-menopausal obesity increased rapidly with cessation of the periods. To these the administration of thyroid is justifiable, but it should be appreciated that by suitable dieting, if the case has not gone too far, all the symptoms can be abolished, and a moderately low basal metabolic rate may right itself in the process. This can never be said of true myxoedema.

It is unnecessary for me to describe in detail the characteristics of the various types of endocrine deficiency. In any case they are so often combined that it is impossible to be certain of the extent to which one of them contributes. Any hereditary factor which is present appears

obesity, with its associated drowsiness and lethargy, has been overcome in a few weeks solely as the result of dieting.

In hypopituitarism of later life the fat is deposited in masses on the body from the waist downwards, and often on the arms. Characteristically, the hands and feet are quite normal, as also are the forearms, ankles, and wrists. The face is not affected proportionately. The great increase in weight which affects many women after they have given birth to one child, and attacks a minority of patients after an acute illness or even operation, is presumably to be attributed to loss of activity of the anterior pituitary. The distribution of fat certainly favours this.

TREATMENT OF OBESITY

Whether endocrine or alimentary, the treatment of obesity is almost entirely a matter of dieting, with the one exception of the fatness of myxoedema. Preparations of pituitary, given by mouth and by injection for weeks on end, have proved valueless. Dr. P. Bishop, experimenting on rabbits with a well-known preparation of whole pituitary, has shown that it is in no way protected from digestion by the use of a keratin capsule, although the same material given intravenously displayed well-marked activity.

DIETETIC TREATMENT

What, then, is the principle of dietetic treatment? It is to give a diet of calorie value below that required for the optimum (not actual) weight of the patient. The

deficiency of calories is made up by the subject's using his own fat. It follows that all forms of obesity can be corrected by dieting. A gentle, but very efficacious diet, for which no calculation is essential, is as follows:*

On Waking.—A glass of water.

Breakfast.—Tea or coffee, sweetened with saccharine; one slice of dry toast, no butter; 3 oz. of cold tongue, boiled sole, haddock, or whiting; fresh fruit.

1 p.m.—A tumbler of water.

Lunch.—4 oz. of chicken or meat (except pork), but no gravy; vegetables as given below, cooked without fat; salad without oil; one square of vita-weat; fresh fruit.

5 p.m.—Tea without milk or sugar.

Dinner.—Bouillon; fish; 2 to 3 oz. of game or meat (except pork), no bread-sauce or bread crumbs; vegetables as mentioned below; salads; one slice of toast; dry wine; fresh fruit; coffee with saccharine.

Condiments Allowed.—Worcester and anchovy sauces, ketchup, pepper, mustard, vinegar, walnut pickle, horse radish, salt sparingly.

Vegetables Allowed.—Green vegetables (except peas), celery, sea-kale, asparagus, and salsify.

Anything not mentioned above may be assumed to be forbidden. This is safe even for elderly subjects with cardiac weakness, although the heart should always be carefully watched during reduction of weight.

A more accurate and much more rapid treatment has been devised by Evans and Strang.¹ Their diet is built up around 1 gram of protein per kilo body weight. This is necessary to maintain nitrogen equilibrium, provided that some carbohydrate is given with it. Without carbohydrate some of the protein would be diverted for its antiketogenic properties. Thus, not less than 0.6 gram is given for each gram of protein. One of these authors' diets which has been quoted recently² allows about 8 calories per kilo instead of the normal 25 to 30 calories. It is very efficacious, though drastic.

Evans and Strang Diet (about 650 calories)

Breakfast.—One egg and 1 oz. of bread.

Lunch.—One egg and 4 oz. of vegetables as below.

Dinner.—One cup of bouillon and 3 oz. of lean meat; 4 oz. of vegetables as below.

Vegetables Allowed.—Lettuce, cucumber, spinach, asparagus, endive, celery, mushrooms, tomatoes, sprouts, watercress, cauliflower, radish, cabbage.

Water as much as needed; no fried foods; a teaspoonful of bicarbonate of soda daily.

It is essential to eat all the amount mentioned in this diet.

The tendency to acidosis is relieved by the use of bicarbonate. Many patients on this diet lose 1/2 to 1 lb.

* Modified diet from Obesity, Leonard Williams.

a day, but may feel listless and suffer constipation. This is the diet used for the patient illustrated above.

Kenyon's modification³ is a useful alternative, though capable of less accurate control. Its food value is approximately 1,000 calories. It allows of high protein, vitamin, and mineral salt content, and leaves the patient to consume his own fat.

Breakfast.—One portion of fruit; one egg and white of one egg; coffee, tea, bread substitute (for example, Heudebert's breadsticks).

Luncheon.—3 oz. lean meat, fish, or fowl; 1/2 pint 5 per cent. vegetables; one portion fruit.

Tea.—Tea.

Dinner.—3 oz. of meat, fish, or fowl and vegetables as at lunch.

9.30 p.m.—Half-cup orange juice; 1 oz. bemax.

In addition, 1 1/2 glasses skimmed milk daily (for calcium content); one capsule haliverol t.i.d. (for vitamin content).

A fruit portion = one orange; half a grape-fruit; one medium apple; two medium peaches; one small pear; one cup strawberries; one cup blackberries.

When the desired weight is attained the diet should be slowly increased with vegetables, and later butter and bread. With the exercise of a little care, weight may be maintained at the ideal figure.

DRUG TREATMENT

Cutting, Mehrtens, and Tainter⁴ investigated the pharmacological action of a yellow dye, alpha-dinitrophenol, which had given rise to fatal poisoning in the munition factories of France during the war. They found that the metabolic rate of animals could be raised 50 per cent. by a dose of 10 mg. per kilo, and over fourfold by larger doses, which would produce death from hyperpyrexia. In human beings the drug in doses of 3 to 5 mg. per kilo daily promptly raised the basal metabolic rate by 40 per cent., and this was accompanied by an average loss of weight of 2 lb. a week. Dodds and Pope,⁵ working with dinitro-o-cresol (dekrysil), found that it would produce the same effect as dinitrophenol, but in appreciably smaller doses—namely, 1 mg. per kilo daily.

Following this publication I tried the drug* in various doses on ten patients. With 1 mg. per kilo body weight given thrice daily, the temperature rose to 101° in two days, and this was accompanied by tremor, tachycardia, and profound malaise. On the third or fourth day the patients (three in all) were yellow in colour, just as if they were jaundiced. This is presumably due to the drug, which is a yellow dye; there was no true jaundice. The pigmentation passed off completely in five days to three weeks; the symptoms subsided in two days after cessation of administration. The remaining seven patients were treated with 1 mg. doses per kilo body weight once a day. No general constitutional effect was noticeable, but weight was lost, if at all, very slowly—for example, 1/2 to 1 lb. weekly.

Judging by Cutting's experiments with the more toxic dinitrophenol given for three months in full doses to animals, it is probable that the regular administration of dinitro-o-cresol is a safe procedure, if given in small doses. Subsequent to my somewhat alarming experiments, an illuminating article by Dodds and Robertson⁶ appeared showing how impossible it was to judge the effect of the substance on the metabolism by temperature or pulse readings; only estimation of the basal metabolic rate can be of help. The metabolic rate can be raised 50 per cent. or more, and yet be unaccompanied by any appreciable alteration in the heart rate or body temperature.

It is view of the fact that it is possible to control obesity even if of frankly endocrine origin by means of dieting

* Supplied by the courtesy of British Cellos Ltd.

alone, it is clearly undesirable to use a drug which is poisonous in doses only a little above those which are effective. In obstinate cases its use may be countenanced, but only when strictly controlled by the doctor, who must be guided by knowledge of the basal metabolic rate. If these capsules be given to patients in bulk it will not be long before one of them doubles or trebles the dose in the same light-hearted way with which thyroid is treated, and then we shall have further scares from the coroner's courts.

CUTANEOUS SENSITIVITY TO ACID-FAST BACILLI IN SUSPENSION

BY

PROFESSOR S. L. CUMMINS, LL.D., M.D.

AND

ENID M. WILLIAMS, M.D.

TUBERCULOSIS DEPARTMENT, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

Muir in India and Mitsuda and Hyashi in Japan have shown that, while advanced cases of nodular leprosy are negative to intradermal injections of "leprolin," a suspension of leprosy nodule in a state of fine division, the mode of preparation of which has been described in their articles on the subject, the more resistant types of anaesthetic lepers react positively to these injections. They report also that, while infants and young children are negative, healthy non-leprosy adults are usually positive to such injections, just as are the more favourable anaesthetic cases. Muir, being anxious to ascertain for certain whether healthy adults in countries where leprosy is no longer endemic reacted as do non-leprosy adults in India, suggested to one of us that he would be prepared to supply "leprolin" if these tests could be performed. We received from Calcutta a supply of Muir's "leprolin" early in October. This preparation, examined microscopically, was found to contain very large numbers of acid-fast bacilli irregularly distributed as single rods, small clumps, and large bundles. Tested for sterility, it gave no growth either aerobically or anaerobically, and a guinea-pig, into which 1 c.cm. was inoculated subcutaneously, has remained free from signs of infection to date.

RESULTS OF TESTS

Through the kindness of Dr. P. K. McCowan and his staff it was possible to carry out these tests on a group of twenty-five non-tuberculous male adults at the Cardiff City Mental Hospital, where successive series of tuberculin tests, designed to throw light on the degree of sensitivity of the population of a mental hospital, have been in progress for some years. As the tests proceeded it became clear that we ought to discover, as far as possible, how far the positive reactions noted were comparable, not only with tuberculin sensitivity, but with sensitivity to a suspension of killed tubercle bacilli, and our tests were accordingly supplemented to allow of this comparison.

On October 30th, 1933, each of the twenty-five men received in the skin of the right upper arm an intradermal injection of 0.1 c.cm. of "leprolin," diluted to 1 in 5 in sterile carbol

saline, and, at the same time, 0.1 c.cm. of a 1 in 2,000 dilution of old tuberculin in the skin of the left arm. The results were observed, and, where positive, measured in extent of raised palpable reaction area, on the third day and afterwards at weekly intervals up to the end of the sixth week.

All those tested gave the usual positive response to tuberculin, which reached its maximum in most cases on the third day, was still well marked, though fading, after one week, and, except in five cases, ceased to be measurable by the end of the second week.

With the "leprolin," thirteen cases were recorded as negative on the third day, and twelve gave more or less marked positive reactions, but the majority had become positive by the end of the first week, five only being recorded as negative or doubtful on the eighth day. All, with the exception of one patient, a Dane, who attained to a "doubtful" only on the eighth day, and was negative at all other dates, were "positive" sooner or later during the time of observation. Their reactions will be considered in greater detail later. The rapid disappearance of the well-marked reactions to old tuberculin, a filtrate containing the soluble elements of acid-fast organisms, as compared with the persistent though less extensive reactions following the inoculation of a suspension of whole leprosy bacilli, led us naturally to attempt a comparison between these latter and a suspension of unbroken tubercle bacilli, killed by heating, as had been the leprosy bacilli. To this end an egg culture of "human" tubercle bacilli, eleven days old, was suspended evenly in distilled water, counted, killed by heating, and diluted with carbol saline so as to contain 160 million bacilli in 1 c.cm. The sterilization was effected at a temperature of between 90° and 95° C. for one hour.

On October 20th, the remains of the tuberculin tests having by now practically disappeared, each of the twenty-five already tested were given an intracutaneous inoculation of 0.1 c.cm. of tubercle bacillary suspension, equivalent to 10 million dead bacilli, into the skin of the left upper arm, thus permitting a comparison with the leprolin reactions, many of which still persisted. As before, the results were read on the third day and at weekly intervals up to the end of the third week.

In examining cutaneous sensitivity to suspensions of acid-fast bacilli, the reactions, both to leprolin and to tubercle suspensions, were found to fall into three types, the distribution of these types, however, being very different in the tested group. These types are as follows:

- Type A—"First high." Maximum reaction on third day.
Type B—"First low." Maximum reaction on eighth day.
Type C—"First negative." Negative on third day developing later.

The distribution of these types to leprolin and to tubercle bacilli respectively was as follows:

Reaction Type	Leprolin		Tubercle Bacilli	
	No.	%	No.	%
Type A ...	6	= 24	21	= 84
Type B ...	6	= 24	2	= 8
Type C ...	13	= 52	2	= 8

It will be noted that the great majority gave their maximum reaction to tubercle bacilli on the third day, just as they had done to old tuberculin; whereas the majority of the group were negative to leprolin on the third day.

The reaction size in millimetres—maximum transverse measurement—is given, as the average for those included in each type, on each day of observation up to the end of the third week, by which date all the reaction areas were rapidly diminishing in intensity.

Average Reaction Size in Millimetres

Reaction Type	Antigen	3rd Day	8th Day	15th Day	22nd Day	No.
Type A ...	Leprolin	9.7	7.5	4.3	4.3	5
	T. B.	17.6	9.5	7.7	4.2	21
Type B ...	Leprolin	6.8	9.5	6.4	6.0	6
	T. B.	9.0	13.0	12.0	8.5	2
Type C ...	Leprolin	0	3.2	3.5	3.8	13
	T. B.	0	5.2	6.0	5.2	2

It will be noticed that, in addition to the fact that, a much larger proportion reacted; in the "Type A" manner, to tubercle bacilli than to leprolin, the reactions to tubercle bacilli were more extensive than those to leprolin in all the types, and on every day of observation. It is interesting to see that the "Type B" reactions persisted longer as a fairly extensive area of inflammatory thickening than the other types, both for leprolin and for tubercle bacilli. "Type C" was characterized by consisting, on the whole, of weak reactors. It is worth noting that the two persons giving a "Type C" reaction to tubercle bacilli were both "C" types to leprolin also, and were the two who reacted least to leprolin, both being so poor in response that it was a matter of some doubt as to whether they should be recorded as positive.

It seems from the results recorded that, in the "healthy" persons tested, the typical reaction to tubercle

bacilli is, like the reaction to tuberculin, one of early development with a maximum on the third day, while the typical reaction to leprolin is characterized by a slow development, being at first negative or doubtful, and only generally reaching its maximum at the end of the third week.

The relative extent and duration of the reactions to tuberculin, tubercle bacilli, and leprolin respectively is illustrated in the chart; but it is to be added that the reactions to tubercle bacilli had all the appearance of persisting quite as long as, or longer than, those to leprolin when the observations were brought to an end at the twenty-second day.

To see how tuberculous patients reacted to a tubercle bacillary suspension it was decided to test the same suspension, diluted so that 0.1 c.cm. contained 1 million bacilli only, in a series of clinically definite cases.

Five adult males with relatively chronic pulmonary tuberculosis, and three children with non-pulmonary lesions, were inoculated intradermally on November 27th, 1933, two children with "doubtful" non-pulmonary lesions being included as controls. All the definitely tuberculous cases

reacted according to the "A" type, while the two "doubtful" children proved negative. Tested with a dilution of 1 in 5,000 of old tuberculin on December 6th, the two "doubtfuls" were again negative, all the definite cases being markedly positive on the third day.

It is to be noted that, where bacillary suspensions were used for intradermal injection, there was a decided tendency to a central necrosis, a small loss of substance at the centre of the reaction area in certain cases, not necessarily those who had reacted most extensively at first. In the leprolin series five showed this central lesion on the twenty-second day, two more on the twenty-ninth, and still another on the thirty-sixth. In the tubercle bacillary series this central necrosis was earlier in appearance and more common, six cases showing it on the eighth day, while a further eleven persons had central loss of substance by the fifteenth day, the remaining eight having unbroken reaction areas up to the twenty-second day, after which observations ceased. By that date the majority of the reaction ulcers resulting from the necrotic process and noted on the eighth day had already dried up or healed, and the leprolin reactions, too, had scabbed over or disappeared by the forty-third day of observation.

SUMMARY OF OBSERVATIONS

The factors determining the responses noted to the intradermal inoculation of heat-killed acid-fast bacillary suspensions in persons free from the signs of clinically active tuberculosis call for further study, and can only be discussed as a part of the larger subject of bacterial hypersensitivity. Here it will suffice to summarize the points brought to light in the series of observations described.

1. The typical reaction to tubercle bacillary suspension resembles the typical intradermal tuberculin reaction in reaching its maximum on or about the third day. It differs from the tuberculin reaction in persisting longer and showing a tendency to late central necrosis. The writers have noted central necrosis as a rare occurrence after intracutaneous tuberculin tests, but these have been marked at the third day at the height of the reaction, whereas the central necrosis caused by bacillary suspension comes on as the initial inflammatory reaction is fading.

2. The typical reaction to leprolin (suspension of heat-killed leprosy bacilli and leprous tissue), when applied to healthy persons in an area free from endemic leprosy, differs from the intracutaneous tuberculin reaction in remaining for some days negative or doubtful, gradually developing to a maximum between the eighth and the fifteenth day, and lasting on for from four to six weeks as a diminishing zone of inflammatory oedema, often showing late central necrosis.

3. Six out of twenty-five persons tested with leprolin reacted to the injection in a manner similar to the usual response to intracutaneous tuberculin or to tubercle bacillary suspension, showing that they were hypersensitive to a bacillary antigen to which, presumably, their tissues were "virgin soil." This result suggests that "group" sensitivity must play a definite part in reactions to acid-fast bacillary constituents.

4. It is of interest that, in two probably non-tuberculous children tested with intracutaneous tubercle bacillary suspension, no reaction was observed either late or early, the bacilli being disposed of without inflammatory response.

THE CAUSE OF HYPERPIESIA

PRESENTATION OF A HYPOTHESIS

BY

C. P. DONNISON, M.D.LOND.

Of the several theories that have been presented as an explanation of the common type of high blood pressure two alone receive an appreciable degree of general support. These are: (1) the toxæmic theory, and (2) the mental stress theory. The toxæmic theory may be subdivided into two groups, according to the suggested origin of the toxin. One suggestion is a focus of chronic infection, whilst the other postulates absorption of derivatives of protein digestion. The mental stress theory maintains that hyperpiesia arises as the result of an over-responsive vasomotor system consequent upon a high-pressure existence or of mental stress.

The aetiological factors established regarding hyperpiesia do not help much towards consideration of these theories, but one such factor, the geographical and racial distribution of the disease, affords some definite facts that require consideration when any theory is presented. The distribution of hyperpiesia is not world-wide. The condition is exceedingly common in Europe and North America. In Egypt¹ it is common among certain classes, more particularly the educated, whilst among the hospital classes it is rare. It is rare among Chinese and Orientals,^{2,3} who have apparently lower average blood pressures than Europeans. Conception and Bulatao⁴ have made similar observations in the Philippine Islands, whilst my own findings⁵ among the natives in Kenya Colony were of the same nature. The native of South Africa apparently only very seldom develops a high blood pressure,⁶ whilst in the African in America there is quite an appreciable incidence of the condition.⁷ The distribution of hyperpiesia throughout the world does not demonstrate a clear racial distribution, but shows an incidence that corresponds more closely with civilization. The African native seems immune from hyperpiesia whilst he lives in primitive conditions in Africa, but when he has been transported to America and adopts a mode of living associated with civilization, he becomes subject to it. Foster records,² among 4,000 hospital patients in China, one case only of hyperpiesia, that of a nurse, a highly nervous woman, who had gone to America to finish her education, and had returned with the habits and attitudes of a "Westerner."

I have stated elsewhere⁸ that my observations amongst African natives afforded evidence that, in my opinion, lent support to the mental stress theory. A consideration of other observers' findings, together with some observations that I have made in general practice in England, have led me to form some tentative conclusions regarding the manner in which mental stress might lead to hyperpiesia. I propose to present my conclusions in the form of a hypothesis, and will subsequently consider the evidence bearing on it.

CANNON'S EMERGENCY REACTION

The theory that mental stress can be held responsible for the development of an established high blood pressure suggests that Cannon's emergency reaction might have a bearing on the problem. Cannon's observations⁹ have demonstrated that a rise in blood pressure occurs in animals as a result of an emotional stimulus, and that such rise serves the purpose of preparation "directed towards efficiency in physical struggle." An animal confronted with a situation embracing features of an emergency receives an emotional stimulus which produces a

characteristic physiological reaction dependent on stimulation of the sympathetic nervous system and an outpouring of adrenaline into the blood stream, and manifested by general vaso-constriction, rise of blood pressure, rise of blood sugar, increased cellular content of the blood, and inhibition of motility and secretion in the alimentary tract. This reaction is essentially a physiological one, and cannot be held responsible for the development of a pathological condition without qualification.

The most outstanding fact known regarding the aetiology of hyperpiesia is its dependence upon civilized conditions for its incidence. Cannon's emergency reaction appears alike in the civilized and the uncivilized. What factor dependent on civilization can lead to a variation in the response to this reaction? Human evolution has reached a stage where the struggle for existence has ceased to be a physical one, and the first contrast in the changing circumstances of human evolution is the fact that Cannon's emergency reaction continues to be called into play, but often is not followed by physical struggle. Crile¹¹ and McDowall¹² have suggested that the muscular activity of the physical struggle that follows an emergency may act as a safety-valve for relief of the rise in blood pressure by causing widespread vaso-dilatation in the voluntary muscles. In civilized conditions this natural safety-valve action often would not arise.

The hypothesis is suggested, therefore, that the development of hyperpiesia depends upon the following sequence of events: (1) repeated mental stimuli bearing factors of "stress"; (2) the induction of Cannon's emergency reaction by such stimuli; and (3) the absence of physical struggle following the reaction. Resulting from the consideration of this hypothesis certain questions arise which require careful consideration.

REPEATED STIMULATION AND PATHOLOGICAL CHANGE

Can repeated stimulation of Cannon's emergency reaction give rise to the pathological changes associated with hyperpiesia?

It is generally accepted that the initial structural changes that arise in hyperpiesia take place in the arterioles, and manifest themselves by hypertrophy of the musculature of the media and also by some intimal hypertrophy. Degenerative changes appear secondarily to the hypertrophy in both intima and media. Turnbull¹³ has indicated that, whilst medial hypertrophy is apparently directly proportional to the height of the blood pressure, intimal hypertrophy is less directly dependent on the height of the blood pressure, and more dependent on other factors, such as age of the patient, and he concludes that intimal hypertrophy and degeneration are a result of, and not a cause of, high blood pressure. It is in the arterioles that the fall in pressure occurs from the arterial pressure of about 120 mm. Hg to the capillary pressure of about 20 mm. It is in the arterioles that the sympathetic vasomotor system exerts its chief influence upon the vascular system.

Cannon's emergency reaction is brought about by an outpouring of adrenaline into the blood stream and by stimulation of the sympathetic nervous system. That excessive secretion of adrenaline can produce pathological changes closely resembling those found in hyperpiesia has been demonstrated by the report of cases of tumours of the suprarenal glands causing a high blood pressure, and in some cases removal of the tumour has resulted in a fall of the blood pressure to normal levels.⁹ That there is an excessive secretion of adrenaline in hyperpiesia is distinctly doubtful. Vaquez¹⁴ first put forward the view that overaction of the suprarenal glands was the cause of hyperpiesis, but this view has been subjected to much criticism, mainly on the ground that several

observers have tried to demonstrate an excess of adrenaline in the blood of patients suffering from established hyperpiesia without success,¹⁵ and transfusion of blood from people with high blood pressure into normal individuals does not lead to a rise in blood pressure.¹⁶ Cannon's experiments have only demonstrated an outpouring of adrenaline as a response to an emergency. Some more recent experiments have demonstrated that, in addition to a rapid response to an emergency induced by the influence of adrenaline, there is a delayed response dependent on sympathetic stimulation and independent of the suprarenal glands.¹⁷ Consequently the failure to demonstrate an excess of adrenaline in the blood of cases of hyperpiesia does not exclude the possibility of Cannon's emergency reaction as a fundamental factor in the causation of that condition.

The effect of repeated stimulation of the sympathetic nervous system has been demonstrated by Goormaghtigh's experiments.¹⁸ By removal of the carotid bodies and section of the depressor nerves he claims to have produced not only a high blood pressure but lesions in the renal glomeruli exactly resembling those found in hyperpiesia. There is no evidence that these structures are interfered with in any way in hyperpiesia,¹⁹ but these experiments, and also the vascular changes in thrombo-angiitis obliterans,²⁰ do show that structural changes can arise from overaction of the sympathetic system.

EMOTION AND THE EMERGENCY REACTION

Is Cannon's emergency reaction produced in human beings by emotional stimuli?

No one would dispute that an emotional stimulus readily gives rise to an increase of blood pressure in human beings. This is a characteristic of all races, irrespective of civilization. The question as to whether this increase of blood pressure is a specific response to an emotion or is part of a more general reaction such as that described by Cannon is not an easy one to decide, as it depends upon demonstration of a coincident rise in blood sugar and other manifestations. Indirect evidence that there is an elevation of the blood sugar in emotional reactions in human beings has been obtained by Folin, Denis, and Smillie,²¹ who demonstrated sugar in the urine in about 18 per cent. of students after they had sat for important examinations. Of seventy students tested, one only had a trace of sugar before the examination, whilst afterwards thirteen showed glycosuria.

More striking evidence of the relation of both blood pressure and blood sugar to emotional conditions was obtained in a case of mine in which a fortunate coincidence enabled me to make a series of observations.

Mrs. P. first consulted me in September, 1929. She was then 24 years of age. She had two children, the younger being 2 months old and breast-fed. She came to me complaining of attacks suggestive of migraine. Blood pressure was found above normal for her age, the lowest readings obtainable being 152/96. Nothing else abnormal was found on examination except a faint trace of sugar in the urine. Owing to lactation it was concluded that the sugar was probably lactose, but the patient was advised to have her urine examined again after cessation of lactation. This she failed to do.

She consulted me again in February, 1932, for further typical migraine. Attacks varied in incidence from about once every three weeks to daily occurrences, and they tended to come on more readily if she was worried. She had had two attacks just prior to the consultation. In between attacks she felt quite fit. On examination she was found to have a blood pressure of 145/100, and glycosuria was present.

Six days later she was seen again. She had had no migraine in the interval. Her blood pressure was found to be 128/85 and the urine contained no sugar. On this occasion close questioning revealed the fact that she had been considerably

agitated and worried, owing to the fact that her mother-in-law, who lived with her, had been somewhat trying and difficult to get on with. The mother-in-law went away about the time of the previous consultation. It was considered that the glycosuria required investigation, so a sugar tolerance test was carried out. Blood sugar examinations were carried out by MacLean's method and revealed the following figures:

	Per cent.
Fasting blood sugar	0.070
Three-quarters of an hour after 50 grams glucose	0.100
One and a half hours after 50 grams glucose	0.088
Two and a quarter hours after 50 grams glucose	0.082

The glycosuria was thus dependent on a low renal threshold, and some subsequent observations confirmed its coincidence with mental stress.

It thus appears that in this case we have mental stress leading to a tendency for migraine attacks, a raised blood pressure, and glycosuria. In the absence of mental stress the blood pressure is within normal limits, and glycosuria does not normally occur. The presence of a low renal threshold afforded the opportunity of demonstrating the fact that the blood sugar rose with the blood pressure and fell with it in response to the emotional condition of the patient, thus suggesting that the rise of blood pressure in response to emotional stimuli is part of the more general reaction as described by Cannon.

REPEATED STIMULATION OF CANNON'S REACTION

What evidence is there that repeated stimulation of Cannon's emergency reaction can produce hyperpiesia? Repeated stimulation of Cannon's emergency reaction should lead to establishment of high blood pressure by means of vaso-constriction in the arterioles, and we should also expect some indication of effects on the blood sugar.

There are theoretical reasons, pointed out by Fishberg,² for supporting the view that vaso-constriction is the essential factor in the pathogenesis of hyperpiesia. The laws governing the flow of fluids through tubes have been studied by Poiseuille, and, though they may not hold exactly for branching tubes, it has been shown that they do apply fairly closely. These laws demonstrate mathematically that the radius of the vessel is the factor, variation of which would have most influence on blood pressure. Vaso-constriction would imply muscular activity, and the pathological finding of medial hypertrophy as the earliest morbid change affords strong support. That overaction of the sympathetic system can lead to a high blood pressure and the morbid changes characteristic of hyperpiesia has already been demonstrated.

Further consideration of the question of the bearing of Cannon's emergency reaction upon hyperpiesia can arise out of the blood sugar changes. If repeated stimulation of the reaction can produce, in certain circumstances, an established rise of pressure, then one would want to know what would happen to the blood sugar. O'Hare²² reports on a series of twenty-three cases of hyperpiesia in sixteen of which he observed diminished sugar tolerance. On the other hand, Marshall²³ records that he could find no relation between blood sugar and blood pressure, but his investigations were carried out on elderly people, all over 65. Musser and Wright²⁴ found marked lowering of sugar tolerance in a group of thirty obese subjects of hyperpiesia compared with a control group of obese people with normal blood pressure. Other references in the literature seem to reveal very varying standards of normality in sugar tolerance, and, when referring to hyperpiesia, are very indefinite regarding the nature and stage of the condition. Marshall has indicated that in elderly people diminished sugar tolerance is usual,

so that conclusions based on advanced cases of hyperpiesia must be accepted with caution. It is the sugar tolerance of the early case of hyperpiesia that might afford information of value regarding the hypothesis, and on this point the literature seems to reveal no definite information. A thorough investigation upon this point has been beyond my facilities, but I have managed to make scanty observations on one case.

Nurse R., a district nurse, who had worked in co-operation with me and who had been overworked throughout the winter, consulted me on March 4th, 1932, on account of headaches, dizziness, and mental depression. The only abnormality of importance that I found was a blood pressure of 170/110. Thinking that I had here an early case of hyperpiesia I took a specimen of blood for examination at between four and five hours after breakfast. Blood sugar was 0.122 per cent. The blood pressure remained high for several days, so I sent her for a month to the South Coast. On her return she felt much better, and her blood pressure was 135/105, so I arranged to repeat the blood sugar estimation under identical conditions. It was 0.058 per cent. (Both analyses were of venous blood.)

To sum up the evidence bearing upon repeated stimulation of Cannon's emergency reaction as a cause of hyperpiesia, theoretical and pathological considerations are considerably in favour of the hypothesis, but confirmation from sugar tolerance in the early hyperpieptic seems at present to be lacking. Literary references seem indefinite and conflicting. One case of my own lends some support to the theory, but clearly further investigation on this point is indicated.

ABSENCE OF PHYSICAL STRUGGLE

What evidence is there that lack of physical struggle, that should naturally follow Cannon's emergency reaction, is an essential factor in the development of hyperpiesia? Attention has already been directed to the suggestion that the physical struggle that usually follows stimulation of the emergency reaction under primitive conditions acts as a sort of safety-valve for the raised blood pressure. Civilization has led to changes in the response to emergencies, which are comparatively infrequently followed by physical exertion. That this factor may be an important one in the causation of hyperpiesia is suggested by the fact that that condition shows an incidence dependent on civilization rather than on race, and on mental rather than on manual labour.

In order to obtain further evidence on this point an experiment was carried out on a volunteer. The aim of the experiment was to arrange to stimulate the emergency reaction and to follow such stimulation with vigorous exercise on one occasion and with rest on another. Then observations were made at intervals on the blood pressure and blood sugar in order to contrast the effects of exercise and its absence on the reaction. It was almost impossible in practice to devise a method of giving on two occasions emotional stimuli that could invoke reactions of equal intensity in a subject who was aware that he was being experimented upon. Consequently subcutaneous injections of adrenaline were given, as by this means stimuli of equal intensity could be applied on two occasions under controlled conditions.

The volunteer for the experiment, a healthy man aged 27, was given a light breakfast. Two and a half hours afterwards he was given a subcutaneous injection of 1/2 c.cm. of adrenaline chloride (1 in 1,000). Blood pressure was recorded before the injection and at half-hourly intervals afterwards for two hours. Blood was taken from a vein for estimation of sugar at the commencement of the experiment and at one hour and two hours after the injection. The blood sugar determinations were made by MacLean's method. In the first experiment, immediately after the injection of adrenaline, the

subject began some vigorous exercise, digging during the first half-hour, a brisk walk during the second half-hour, and more gentle walking in the remaining intervals. The exact figures obtained are shown in the following table.

EXPERIMENT 1.—With Exercise

	Systolic Blood Pressure	Diastolic Blood Pressure	Blood Sugar— Per cent.
Before injection ...	132	85	0.097
½ hour after injection ...	135	85	
1 hour after injection ...	118	78	0.097
1½ hours after injection ...	116	78	
2 hours after injection ...	116	76	0.085

EXPERIMENT 2.—With Rest

	Systolic Blood Pressure	Diastolic Blood Pressure	Blood Sugar— Per cent.
Before injection ...	118	78	0.092
½ hour after injection ...	135	70	
1 hour after injection ...	128	75	0.125
1½ hours after injection ...	124	76	
2 hours after injection ...	115	80	0.105

The first blood pressure reading in the first experiment was apparently elevated, evidently due to apprehension, as subsequent observations revealed that the normal blood pressure of the subject of the experiment was nearly constantly about 118/78. In both experiments the systolic blood pressure rose to about 135 mm. shortly after the injection. With exercise, however, it fell to normal within one hour, whereas without exercise it fell much more gradually, and did not reach a normal figure until two hours after the injection. This demonstrates how exercise acts as a sort of safety-valve after an emergency reaction in leading to a rapid lowering of the blood pressure to normal levels. No very definite variations of the diastolic blood pressure appear in the experiment. Blood sugar estimations serve as a useful confirmatory observation regarding the effects of the reaction, and effects similar to those on the systolic blood pressure are noted.

The subjective sensations of the subject were interesting. The dose of adrenaline was quite sufficient to produce subjective symptoms, such as slight shakiness and a sensation of being "strung up" in both experiments within the first half-hour. In the experiment without exercise these symptoms were definitely more marked and of longer duration, lasting about an hour.

These experiments demonstrate how stimulations of the emergency reaction without subsequent muscular exertion, as must occur repeatedly in the lives of many civilized human beings, must have effects differing from those obtained when such stimulation is usually followed by physical struggle. The difference may probably be more marked than this experiment would suggest, since these results are demonstrative only of the effects of adrenaline, whereas a delayed response dependent on sympathetic stimulation and independent of the suprarenal glands also occurs,¹⁷ and this may conceivably result in still further delay in the fall of the systolic blood pressure to normal levels in the absence of physical exercise.

NATURE OF STIMULUS TO CANNON'S REACTION

What is the nature of the stimuli required to induce Cannon's emergency reaction in civilized conditions?

The hypothesis here presented implies that the causation of hyperpiesia is essentially psychological. An analysis of the factors requisite for the induction of Cannon's emergency mechanism reveals three stages as defined by

psychologists: first, cognition or perception, by means of one or more of the sensory systems, that an emergency has arisen; secondly, affection; and, finally, conation—a striving to influence factors for the benefit of the individual concerned. Cannon's emergency reaction is essentially a part of conation, in that it prepares the individual for dealing with an emergency by physiological anticipation of the imminent need for violent physical struggle. It will be helpful to consider the nature of the stimuli required under civilized conditions in the light of this psychological classification. Excessive induction of Cannon's emergency reaction would imply an excess of one or more factors in the process of cognition, affection, and conation.

Cognition depends on (1) environmental factors bearing features of the nature of an emergency, and (2) sensory perception thereof. Disorders of sensory perception involving an excess of cognition independent of environment would imply some form of delusions, and need no further consideration as a factor bearing on the aetiology of hyperpiesia. Environmental factors bring up many considerations. It has already been mentioned that civilized conditions have led to circumstances that favour the development and dissemination of factors calculated to present features of an emergency. Occupations involving heavy responsibility are clearly going to be fruitful in suitable cognitive factors, often referred to as factors involving mental "stress." The process of affection involves association of the emergency factors perceived with past experience, by which we recognize that a given combination of sensory perceptions implies something that is potentially harmful. This association with a past experience may be a conscious association, as when an emergency indicates a known danger; or it may be an unconscious association, such as may occur when the memory of an unpleasant experience has been repressed into the unconscious, but association invokes the emotion coupled with that experience. This is the essential mental process at work in psychoneurosis, and hence it would appear that in a condition of psychoneurosis, and particularly in that type referred to as an anxiety state, the disordered process of affection would increase the facility for suitable stimuli.

The stage of conation leads us into the realm of physiology, and manifests itself by a characteristic response to the condition that invokes the appropriate stages of cognition and affection, or, in other words, a conditioned reflex, as described by Pavlov, is induced. This reflex, or Cannon's emergency reaction, serves the purpose of preparation for physical struggle, which under primitive conditions is usually necessary when an attempt is made to influence the environmental factors in favour of the individual. This reflex reaction is subject to certain principles and laws governing reflex actions, among which facilitation, or "Bahnung," is of special significance in this instance. According to this, when an impulse has passed once through a certain set of neurones to the exclusion of others it will tend, other things being equal, to take the same course on a future occasion, and each time that it traverses this path the resistances in the path will be smaller.²² This establishes on a scientific basis what the clinician refers to rather loosely as vasomotor instability. Often repeated stimulation of the emergency reaction would lead to a lowering of the threshold for that reaction and a heightening of the response to it. This would account for the variability of the blood pressure that is so frequently observed in the earlier stages of hyperpiesia, usually manifesting itself as an excessive reaction to emotional stimuli.²³ It has been suggested by Millais Culpin, in connexion with the causation of asthma, that an originally emotional stimulus could evoke a reflex

response by which a number of physiological reactions become abnormally labile. Such an explanation of a psychological aetiology of a physical condition is clearly capable of wider application.²⁴

To summarize considerations of the stimuli that would induce Cannon's emergency reaction and hyperpiesia in civilized conditions, it seems that the main initiating factors would be environmental conditions involving "stress" or heavy responsibility, and psychoneurosis. It would appear that these two factors would act as alternatives, though in any given case some element of each could be present. Vasomotor instability or facilitation of the emergency reaction serves as an important accessory factor in the causation of hyperpiesia, but it is probably incorrect to regard it as a primary factor. The readiness or otherwise with which facilitation would supervene in a given instance might determine whether, in a given set of circumstances, a high blood pressure would develop or not.

CLINICAL EVIDENCE FOR HYPOTHESIS

Having considered theoretical implications of the hypothesis in the last section, I shall now consider to what extent those implications are supported by clinical evidence. It is often stated by clinicians that high blood pressure is most prevalent among mental workers, and the city business man is often cited as the typical example. Literary evidence in support of this fact is scanty. In my own series of 117 cases collected in general practice sixty-three were in women whose occupations were household duties, in which the degree of mental stress involved is difficult to estimate. Of the remaining cases thirty were in occupations in which there was clearly an element of mental stress (for example, manager or owner of private business, nurse, accountant, teacher), whilst only two cases occurred in heavy manual workers.

With regard to the incidence of psychoneurosis in the early stages of hyperpiesia, literary references afford information of value. O'Hare, Walker, and Vickers²⁵ report a series of cases in which there was an early history of nervous temperament or vasomotor weakness in 42 per cent. and, in a smaller series, studied in greater detail, in 87 per cent. A control series of people with normal blood pressure gave 23 per cent. of cases with such a history. Stieglitz²⁶ describes several cases of patients complaining of physical distress dependent upon psychic strain in whom marked emotional rise of blood pressure was recorded. Ayman and Pratt²⁷ stress the fact that the earlier symptoms in hyperpiesia are of psychic origin, and that emotional stress is usually found as an antecedent. Davis²⁸ and Riseman and Weiss²⁹ make similar observations. Barton Hall³⁰ investigated the blood pressure in various forms of psychoneurosis, and demonstrated that in neurasthenia and psychasthenia blood pressure is abnormally low, whilst in cases of prolonged mental strain and anxiety neurosis it may be abnormally high, falling with treatment of the neurosis. In my own series of cases a perusal of the histories reveals the existence of symptoms suggestive of past neurosis in 65 per cent. In many cases in which no such record exists I find that they are advanced cases that have probably been established for many years, and no report has been made of inquiry into more remote history of symptoms of neurosis. I am of the opinion that if such inquiry had been made in every case the percentage would have been distinctly greater.

As has already been mentioned, Ayman²⁶ has drawn attention to the lability of the blood pressure in early stages of hyperpiesia. Backer³¹ mentions the same fact. Both authors suggest that the hyperpiesia subject has a

vegetative nervous system which reacts excessively to slight stimuli. Ayman adds that

"in a limited number of observations it has seemed to me that the patient with essential hypertension tends to walk and work faster than the average; he is often more sensitive and more easily embarrassed than the average. Whereas the blood pressure of the normal person may rise from 10 to 30 mm. of mercury during excitement, that of the hypertensive patient more often rises from 30 to 100 mm."

Barton Hall has drawn attention to the variability of the blood pressure in anxiety neurotics. In my own series of cases I find notes of fairly decided variability of the blood pressure recorded in 54 per cent. In many of the remaining cases it was probably observed but not recorded, as it used to be my custom to ignore an initially high reading and to record only the lowest pressure obtained after several observations.

In the last section, when considering the stimuli likely to lead to development of hyperpiesia, I indicated how an occupation involving mental stress and psychoneurosis were to be regarded as alternative factors in aetiology, but vasomotor instability was probably itself not a primary factor, but was dependent for its development on one of the other factors. Consequently it would be helpful to analyse my series of cases regarding an occupation involving mental stress and a history indicative of psychoneurosis as alternatives. It was found that a number of those cases in such occupations presented no history of psychoneurosis. Grouping the two factors together, eighty-nine out of the 117 patients gave a history of one or both factors (76 per cent.). In the remaining twenty-eight, nine presented evidence of vasomotor instability, which some authors have accepted as evidence of nervous instability, and which at all events suggests that more careful inquiry would probably have led to evidence of this being found. The figures quoted in this series have been compiled from ordinary case notes collected over a period of four years. During the major part of this period the present inquiry was not foreseen, and no special attempt was made to elicit a history of significant symptoms. It is noteworthy that a number of the remaining twenty-eight cases were of elderly people in whose notes no evidence was afforded regarding conditions which would have been remote; sixteen of them were 65 years of age or over. There remained a small, clearly defined group of cases that fail to present features that support the hypothesis presented. These cases were in women at or after the menopause in whom adiposity was a characteristic feature. It would appear that the possibility of a different aetiology might have to be considered in this type of case.

SUMMARY

1. A hypothesis as to the causation of hyperpiesia is presented for consideration. This hypothesis suggests that hyperpiesia arises as a result of: (1) repeated mental or emotional stimuli bearing factors of "stress"; (2) the induction of Cannon's emergency reaction by such stimuli; and (3) the absence of physical struggle following the reaction. Evidence bearing on the hypothesis derived from literary references and from personal observations is reviewed.

2. The importance of the absence of physical struggle is demonstrated by a consideration of the geographical distribution of hyperpiesia. An experiment is described comprising observations on blood pressure and blood sugar after injections of adrenaline. It is demonstrated that the rise of blood pressure and blood sugar that follows an injection of adrenaline falls to normal levels much more rapidly if the injection is succeeded by vigorous exercise than in the absence of this.

3. Detailed consideration is given to the nature of the stimuli required to induce Cannon's emergency reaction in civilized conditions, and it is suggested that such stimuli either are mental stress in a life involved in heavy responsibility or arise as a result of a psychoneurosis. Vasomotor instability, which often appears to occur in the earlier stages of hyperpiesia, probably results from facilitation, and is dependent for its development on one of the foregoing factors.

At a meeting of the New York Board of Health, on March 20th, the whole question of bathing in the tidal waters of New York City was considered. It was shown that there was as yet no agreement among sanitary authorities as to the bacterial standards which should be adopted for bathing beaches. A study of the 557 cases of typhoid fever in the city last year showed that only fifty-one of these were ascribed to bathing in polluted waters. In practically all of these cases the victims had bathed in Jamaica Bay, Gravesend Bay, or the Harlem River, areas in which the water is heavily contaminated with sewage. A report concerning the sanitary conditions and bacteriological examinations of the waters at the Bronx beaches and Orchard beach was considered. This, together with the fact that the local waters are so largely diluted with the waters of the Sound, led the Board to sanction a continuance of bathing at these beaches, at least for the coming summer. The Board directed that a determined effort should be made to control direct sewage pollution of bathing beaches generally. It also decided that sanitary and bacteriological surveys should be undertaken during the summer in order to gain more definite information as to the bacterial standards to govern the waters of bathing beaches.

CERTAIN INJURIES OF THE KNEE-JOINT*

BY

T. P. McMURRAY, M.Ch., F.R.C.S.Ed.

HONORARY ORTHOPAEDIC SURGEON, NORTHERN HOSPITAL, LIVERPOOL;
DIRECTOR OF ORTHOPAEDICS AND LECTURER IN
ORTHOPAEDIC SURGERY, LIVERPOOL
UNIVERSITY

The injuries and strains sustained by the knee-joint are legion, and their signs and symptoms are often so indefinite that a diagnosis is made with the very greatest difficulty, and with no great confidence. Indeed, it is because of the medical man's want of confidence in his knowledge that in many cases the patient turns away from the qualified and seeks the unqualified practitioner. There is no doubt that we of the medical profession are very largely to blame for this loss of confidence on the part of many members of the general public. Instruction in joint surgery is not given the prominence it deserves in our medical education. Our surgical teachers have for the most part stressed the great advances in abdominal surgery, and the newly qualified doctor is allowed to find out for himself what he considers the best methods of dealing with joint lesions. Fortunately there has been a great improvement in this branch of teaching during the past ten years, but much more is necessary before we cease to hear what was told me by two patients during the last fortnight. They stated they had been to unqualified practitioners, but added in explanation: "Of course, my doctor acknowledges he does not know anything about bones and joints."

We must not be content with this one-sided knowledge of the human body and its ailments; we must not only recognize the lesion which is present, but must know the best method of correcting it. It is only when we have a sure knowledge of ourselves that we are able to convince our patients of our ability to give them the correct form of treatment, and so wipe away this slur from our profession.

I now propose to discuss in turn the different types of lesions to which the knee is subject.

CRUCIAL LIGAMENTS

These ligaments, which may be taken as the sole representative of the normal bony interlocking in a large weight-bearing joint, are usually injured only as a result of very severe trauma, and such an injury is diagnosed by the possibility of an abnormal amount of active or passive gliding of the tibia on the femur. In no other lesion of the knee-joint is speed so essential in making a correct diagnosis and starting treatment, because the prognosis depends largely upon the time which elapses between the accident and the commencement of treatment. When the knee is flexed to an angle of 45 degrees both anterior and posterior crucial ligaments are relaxed, and a partial or complete rupture of either crucial ligament is best treated by prolonged immobilization of the knee at this angle for a period of three or four months.

If the ligament is completely torn and the ends separated from each other this method of immobilization is bound to fail, but fortunately in the great majority of cases the rupture is not complete, and in my personal experience there have been several cases of clinically complete rupture in which this treatment has resulted in a sound joint with no sign of ligamentous weakness. There are other cases, however, for which adequate treatment has not been adopted, or in which it has failed, and the problem arises whether any operative measures can be employed to suture or replace the injured ligament with other structures.

Many ingenious operations have been devised to deal with the condition. These have varied from the suture of the ruptured ligament *in situ* with catgut, silk, or even wire, but the end-results in every case have been disappointing. When catgut has been used the result has usually been a slow absorption of the gut and reappearance of the primary laxity. When silk or wire has been used the result has been even more unsatisfactory, because the presence of these foreign bodies has led to the formation of a definite osteo-arthritis and an increase of disability. Hey Groves devised an ingenious operation by which, through drill holes in the femur and tibia, a portion of the ilio-tibial band—which had been rolled into a cord—was used to replace the injured ligament, but unfortunately this new ligament gradually stretched, and after twelve months or so the laxity again appeared. In fact no satisfactory and reliable operative measure has been devised by which we can replace the action of either crucial ligament after a complete rupture. We are left, then, with the problem of an unstable knee in which at any moment the tibia may shoot forwards on the femur. This instability may be somewhat relieved by the wearing of a knee cage, which will prevent the shooting forwards, but the wearing of this inevitably leads to wasting of the important muscle groups surrounding and governing the joint. It is far better to attack the instability by developing these muscles by voluntary exercises and carefully regulated massage, which usually results in an astonishingly sound and useful knee-joint. When, however, both crucials are divided, or for any reason it is impossible to produce a sound muscular control, the problem of arthrodesis of the joint has to be considered very carefully.

INTERNAL LATERAL LIGAMENT

When any ligament is strained or ruptured the lesion usually occurs, not in the middle of its course, but near one or other of its bony attachments. This is a point of the very greatest clinical importance, for after a strain or tear of the internal lateral ligament the area of tenderness is found at the femoral or tibial insertion, more often the former.

Strains or tears of the ligament should be treated by complete rest for a period of fourteen to twenty-one days, during which the newly forming scar tissue is allowed to consolidate, but after that time complete fixation and want of use are inadvisable. In other words, the patient should then be allowed to walk and exercise the leg, but with the proviso that the injured ligament is protected from all strain. The increased circulation caused by use is helpful in strengthening the union and in the prevention of adhesions round the injured area. While this line of treatment is quite satisfactory in those cases where the injury of the ligament is only partial, it will fail when the rupture is complete. Just as in the instance of rupture of the crucials, simple suture of the divided ligament usually leads to a disappointing result. In such a case the ruptured ligament may be reinforced by the tendons of the neighbouring semitendinosus or gracilis muscle, which are freed from the fascia holding them to the posterior aspect of the internal condyle, and one or both are implanted into a deep groove cut into the internal condyle of the femur. In this manner the muscles become inserted into the femur and not into the tibia, their lower portions being sutured to the substance of the injured ligament and reinforcing this structure. There are, however, cases in which, after a strain of the knee, tenderness is found over the middle of the internal lateral ligament about the level of the knee-joint. These are not true cases of strain of the ligament, but strain of the attachment of the internal semilunar cartilage to the deep aspect of the ligament, and they should be treated for this lesion.

* Lecture delivered to the Nottingham Medical Society, November 22nd, 1933.

We can say, then, that in any recent injury of the internal lateral ligament, in addition to the instability of the joint, there is tenderness, either at the insertion of the ligament into the femur or into the tibia. Later, when the inflammatory reaction has disappeared, this tenderness will also disappear, and only a greater or less amount of laxity is left to indicate the previous lesion.

EXTERNAL LATERAL LIGAMENT

Injuries and tears of this ligament are much rarer than those of the internal, probably because in most people there is a slight tendency to knock-knee, and because the external lateral ligament is protected by the powerful ilio-tibial band of fascia lata, and the strong tendon of the biceps femoris. These, of themselves, are almost capable of supporting the outer side of the joint without the help of the external lateral ligament. If, however, the ligament is strained the tenderness is not usually so marked, and this absence of tenderness is probably more apparent than real, owing to the difficulty of finding the tender spot which lies under the cover of these protecting structures. Just as in the case of the internal lateral ligament, a strain or tear is accompanied by tenderness at the insertion of the ligament into the femur or the fibula, the latter being the usual site of the lesion. Strains of the internal lateral ligament are frequently accompanied by strains, or displacements, or even tears of the internal semilunar cartilage, because of the close association of the two structures, but similar injuries of the external lateral ligament are not generally associated with any lesion of the underlying meniscus, because there is no definite connexion between the two structures.

SEMI-LUNAR CARTILAGES

By far the commonest derangements of the knee-joint are injuries or displacements of one or both of the semilunar cartilages. These two fibro-cartilaginous bodies are placed between the articular margins of the femur and tibia, apparently in order to deepen the surface of the tibia on which the femur articulates. They are both firmly attached to the upper surface of the tibia, firstly by the very firm attachments of their anterior and posterior horns to the upper surface of the bone, and secondly, along their periphery to the non-articulating circumference of the tibia by short fibrous bands known as ligamenta coronaria. In addition, the internal cartilage has the accessory attachment to the deep surface of the internal lateral ligament already mentioned, and the external cartilage sends some fibres into the posterior crucial ligament.

The two cartilages follow very closely all the movements of the head of the tibia, but there is also permitted a slight gliding movement of both cartilages on the upper surface of the bone. In the normal knee-joint this movement is very slight, but where there has been repeated effusion into the joint, and there is a generalized ligamentous laxity, the movement may be very definitely increased.

We know certain facts regarding the mechanism of cartilage injury, but there are many points on which we cannot at present dogmatize. Twists or strains of the joint may cause injury of a cartilage, usually the one on the side towards which the strain has been directed. Thus, if the knee is strained on the inner side the internal cartilage may be injured, and similarly the external cartilage may be injured by a strain applied to the outer side of the joint. Such a displacement or injury of the cartilage never occurs, however, unless the knee-joint is flexed at the time of receiving the strain. The reason for this is obvious—the cartilages are so firmly fixed to the head of the tibia that they follow that bone in all its

movements. If, however, the knee-joint is bent at the time of receiving the strain, then a lateral or rotary strain on the joint may easily displace the cartilage from its attachment to the tibia, or may cause a definite bursting strain of the cartilaginous fibres. A close study of the histories of patients suffering from lesions of the semilunar cartilages will soon convince us that these injuries always occur when the knee-joint is in a position of flexion.

DISPLACEMENT OF INTERNAL CARTILAGE

Let us take a textbook description of a displacement of the internal semilunar cartilage, which is by far the commonest lesion.

The story is that whilst the knee was in a position of flexion the foot was suddenly twisted outwards, or the femur twisted inwards, and the patient felt a sudden acute pain in the antero-internal aspect of the joint, so that he was unable to bear his weight on the leg, and fell down. On attempting to rise, straightening of the knee may or may not have been possible, according to whether the cartilage had in the meantime remained displaced or had gone back into its normal position. This trauma was followed in a few hours by swelling of the joint, which gradually disappeared in the course of a week. At the end of that time the joint appeared normal, except, possibly, for some tenderness on pressure over the antero-internal aspect, just to the inner side of the ligamentum patellae and post-patellar pad. This displacement may only have occurred once, but usually the primary injury was the precursor of many more of a similar nature, each one occurring with slightly less cause than the last and being followed by less reaction in the joint, as indicated by the swelling. In the intervals between the occurrences no gross abnormality can be found in the joint. There may be tenderness on pressure over the antero-internal aspect, but there is no sign apart from the fact that the patient usually says the joint feels unstable and likely to give way on any similar twist.

Here the diagnosis must rest on the history, on the localized tenderness, and possibly, if we are lucky, on seeing the patient directly after one of these displacements has occurred.

DISPLACEMENT OF EXTERNAL CARTILAGE

The story of a displacement or injury of the external cartilage varies very little from that of an internal, except that the knee—again in flexion—has been twisted in the opposite direction, so that the tibia is rotated inwards, or the femur outwards, with the result that the knee is useless and there is pain on the outer side at the joint level. The subsequent story, however, is different. "Locking"—by which we mean the impossibility of straightening the joint—is extremely rare, and subsequent displacements cause a "uselessness," or feeling of extra weakness of the joint rather than the painful locking seen in the case of the internal cartilage. Sometimes there is, in the case of the external cartilage, an additional sign of "clicking," which is of the greatest help in diagnosis. This is a definite and loud click, which can be felt, or even heard, when the joint is straightened. There are two important points to be noted in regard to this diagnostic click: (1) it always occurs at the same angle of flexion of the joint, and (2) this angle is usually the last 10 degrees of full active extension.

DIAGNOSIS OF CARTILAGE LESIONS

I have deliberately gone over these signs at length because they are the only indications of cartilage trouble which are given in our textbooks, and apparently without their presence we are supposed to consider there can be no cartilage lesion.

Let us consider these signs in detail. The only way in which we can mechanically reproduce the series of signs and symptoms of a displaced internal cartilage is

by having the whole or part of the anterior end of the cartilage bent backwards and reduplicated, so that it acts as a wedge between the femur and the tibia when an effort is made to extend the leg. From this we must deduce that either a lesion of the internal cartilage never occurs behind the level of the internal lateral ligament, or if, as we know, such does occur, then its diagnosis without inspection *in situ* is impossible. In regard to the click, or cluck, sometimes caused by the abnormal external cartilage, this can only—on mechanical grounds—be due to the sudden squeezing outwards from between the extending bones of a cartilage with abnormally lax attachments. I have had the opportunity of examining the mechanism of its production on many occasions at operations, and in my experience the method of production has always been the same.

We are left, then, in a very unsatisfactory state. A lesion of the middle or posterior end of the internal cartilage, or a tear of the external cartilage, will certainly not give these classic signs and symptoms; but, nevertheless, they have an equally definite series of signs and symptoms which we must know and appreciate before we can consider ourselves capable of dealing with the various derangements of the joint. The site of a lesion in a cartilage depends, to some extent, upon the angle of flexion of the joint at the time of the occurrence of the original injury. Thus, if the joint is slightly flexed the lesion is usually towards the anterior end, while the more flexion present in the joint the further back is the site of the lesion. This rule is not invariable, but at least it is roughly reliable. Splits of the cartilage may occur at any spot. They start from the inner sharp edge of the cartilage and extend longitudinally, and as the cartilage itself is entirely avascular there is no chance for such a broken piece to join with the rest of the cartilage, no matter how long the joint is kept at rest after the original injury. Each twist of the joint leads to a further splitting of the cartilage, so that the pedunculated mass gradually becomes larger and the disability caused by it more definite. It is not usually large enough to cause locking, whether it is situated in the anterior or posterior section of the joint, but when it is nipped between the femur and tibia it does cause pain, discomfort, and a transitory weakness frequently followed by a synovitis. Similarly, a "bucket-handle" split may occur in either cartilage, and the inner portion may not be sufficiently thick to produce a definite locking of the joint, or, indeed, it may be displaced so far to the middle line that it lies between the condyles of the femur and so allows the movements of the joint to occur in an almost normal manner.

ELICITATION OF A SPECIAL SIGN

The problem before us is whether it is possible to diagnose these injuries to the cartilage, both as to their nature and site, and whether this differential diagnosis is possible at any time, and not only on the occasions when the locking or sudden spasms of pain give us some indication as to the nature of the lesion. In answering these questions we have certain facts to go upon. The first is that each time the torn or broken portion of cartilage is nipped between the femur and tibia a considerable amount of pain is caused to the patient, who can always say whether the spasm or pain was similar to that which occurred previously. If, then, it were possible so to manipulate the joint that the injured cartilage, or portion of cartilage, was nipped between the bones, and pain was caused similar to that usually experienced, it is probable that the same mechanical disturbance had occurred in each case. Such a manipulation can be carried out comparatively easily if we remember the mechanics of the joint.

If the knee-joint is first fully flexed so that the heel is placed almost on the buttock, then abduction of the leg and external rotation of the foot will bring to bear on the internal cartilage the exact same strain as occurs in the ordinary accident when an internal cartilage is displaced or torn. With the foot and leg held in this relation to the thigh, the knee is then slowly extended. If there is a lesion of the internal cartilage at any spot from the level of the attachment of the internal lateral ligament backward, a distinct click will be produced when the femur passes over the site of injury in the cartilage.

This manipulation can also be carried out in the diagnosis of lesions in front of the middle of the cartilage, but for obvious mechanical reasons the test is not so reliable in this situation, and is, in fact, not often necessary because the history and clinical signs are so much more definite and clear. Similarly, lesions of the external cartilage may be examined in almost the same way; after full flexion the joint is straightened with the leg adducted and internally rotated.

There are certain provisos to be remembered in carrying out this test: (1) in the knee of a child a click may frequently be produced in a perfectly normal knee-joint; (2) this may also be possible in some adults in whom there is ligamentous laxity without any other lesion of the cartilage; but if a definite, painful click can be produced on several occasions with the knee at the same angle of flexion, then it is more than likely there is a lesion of that particular cartilage at that spot. Once learnt, the test can easily be carried out, but it requires a considerable amount of "knack" before satisfactory results can be obtained, and practice is the only way in which one can become proficient. It is necessary to note the exact angle of the joint at which the clicking occurs, and whether it occurs at one or two angles—the latter usually indicating the "bucket-handle" type of lesion.

TYPICAL AND ATYPICAL CASES

The test is of little or no value in the typical case in which there is a lesion of the anterior end of the cartilage. The story here is so clear: the patient describes so definitely the site of pain, there is the usual area of tenderness, and there has been the usual history of locking and unlocking. But these classical cases do not make up the whole field of cartilage troubles. At least one patient in three comes with the story that as he is walking along something suddenly gives way in his knee; there is pain, and he either falls or saves himself with an effort. On close questioning he states that the pain occurs somewhere inside the joint. When asked to localize the spot he places both hands over the joint and again says, "It is somewhere-inside." No tenderness can be found, and probably very little swelling, while usually there is never any locking of the joint. This is the type of case which seems to me to present the greatest difficulty. Nothing can be found by the ordinary methods of examination—x rays, etc. Are we then to say the man probably has an internal derangement of the joint, possibly a cartilage, and advise an exploratory arthrotomy, or else condemn him to the massage department?

If there is a lesion of the posterior end of either cartilage an exploratory arthrotomy cannot possibly do any good, because it is impossible to see the posterior ends of the cartilage *in situ* from any incision on the anterior aspect of the joint. In my experience an exploratory arthrotomy is never advisable as a method of diagnosis in lesions of either cartilage. As far as the massage department is concerned, it is already far too well patronized. We find hidden in its soothing care many types of case more suitable for active surgical treatment, and there seems little object in adding to their number. If there is a definite cartilage tear or

displacement massage cannot cure it, and its practice can only postpone the form of treatment likely to benefit the patient.

GENERAL INDICATIONS OF TREATMENT

To me the greatest difficulty in the treatment of knee-joint injuries is the diagnosis. Once this has been settled satisfactorily the carrying out of treatment is comparatively easy. Let us take a simple illustration. A patient has a lesion confined to the posterior end of either cartilage, and on opening the joint in one of the usual positions on the anterior aspect it is seen that the cartilage is apparently normal and undamaged. This is the time when certainty of diagnosis is essential, as without it we are groping in the dark and probably doing more harm than good. Diagnosis should be made before and not after opening the joint. In fact, unless it is made beforehand, opening of the joint will, in all probability, only add to our confusion. A careful examination of the story, good x-ray photographs, and an examination for localized tenderness will help us, but if these are not sufficient a careful manipulation of the joint will nearly always enable us to clinch the diagnosis.

LOOSE BODIES

There are certain errors into which we may fall, and the first of these is in regard to loose bodies. These masses of cartilage, or cartilage and bone, or calcified cartilages, are derived from a variety of sources. They may come from the edge of the articular surface, as a result of a direct blow; or from the substance of the articular surface, as a result of osteochondritis dissecans; or from the development of fibrotic changes and calcium deposition in hypertrophied synovial fringes. In whatever way they are developed they may cause signs and symptoms very much like those of a broken or displaced semilunar cartilage. There is the same unexpected acute pain in one or other side of the joint. There is the same "locking" of the joint, followed by unlocking and usually synovitis; but there is one definite difference. If the body causing these symptoms is really loose then the locking may occur on either side of the joint. If the locking always occurs at one spot then the "loose" body is not really loose but pedunculated, and may be found where the signs and symptoms indicate its presence.

ADHESIONS

A damaged or loose semilunar cartilage may be diagnosed in error when the disability is really due to the presence of adhesions in the capsule or round the attachment of the cartilage. When the capsule of the joint or the attachment of the cartilage to the upper surface of the tibia is stretched beyond its normal capacity there usually follows a considerable amount of inflammatory reaction, either localized to the injured tissues or generalized in the joint as a synovitis. When this inflammatory reaction disappears the distended tissues gradually fall together and may become adherent to each other. In this way, owing to binding together of capsule or synovial membrane, the usual range of movement in the joint is limited. Attempts to carry out the normal range of movements may pull on these adhesions and cause symptoms and signs very much like those of a lesion of the subjacent cartilage. When the adhesions are present over the antero-internal aspect of the joint, rotation of the leg outwards may cause symptoms exactly like those of a displacement of the anterior end of the internal cartilage. There is the sudden acute pain, and on account of the tenderness and pain the patient cannot extend the leg, so that the joint is apparently "locked." There may be a little synovitis, although this is never present

to any great extent, and a similar twist may produce the same symptoms on subsequent occasions. There is, however, one definite point of difference in the story. Although there is the sudden apparent locking, this is never followed by a sudden unlocking and freedom of the joint, as we find in cases of lesion of the semilunar cartilage. In cases of adhesions straightening always comes slowly, as the inflammation diminishes.

It is essential for us to appreciate these different conditions, because in the case of a recurrent displacement of a loose or broken cartilage only removal of the cartilage is really satisfactory. In the case of adhesions a gentle manipulation, under anaesthesia, is usually all that is required to produce normal function in the joint, and for the sake of our reputations we must be able to diagnose those cases which are likely to be a success in the hands of a manipulator, qualified or unqualified.

OPERATIVE APPROACH

The prognosis in regard to knee-joint lesions depends upon the general condition of the joint. If there is no trace of osteo-arthritis, if there is no abnormal ligamentous laxity, and if there is no long-standing chronic synovitis, then excision of an abnormal cartilage will leave a joint which is little removed from the normal. In this removal of the offending cartilage many points are raised as regards the technique and the extent of operation to be carried out. There are certain points on which we are all agreed. First, the incision must be so planned that none of the important ligaments round the joint are injured, and for this reason we use an incision on the anterior aspect between the patella and the internal or external lateral ligament. Secondly, we must consider the length of the incision. There are two schools of thought—those who believe in a large incision through which the operative field can be widely inspected, and through which any other abnormality in the joint can be examined, and those who use the smallest incision which is compatible with free access to the field of operation. I myself am a firm adherent of the latter school of thought, because a very long incision does not necessarily give any better view of the operative field, and the most important feature of the incision is not the length but the site. The reason why, in my opinion, a long incision into the capsule of the joint is detrimental is because such an incision is in many instances followed by synovitis, which recurs again and again as a result of the most trivial strains.

An illustration of this is the case of a footballer I saw recently. He had had a broken internal semilunar cartilage removed in its entirety through a long incision, and during the past year he had been trying to get fit to return to football. Each time he began to train the knee swelled up afterwards, in spite of the fact that the muscle development had been restored to its pre-accident condition. There was no suggestion that a piece of the cartilage had been left in, or that there was any other intra-articular lesion, but only that the long wide scar on the capsule and the synovial membrane had led to a laxity and a loss of the normal absorptive process of the synovial membrane, so preventing the full restoration of function in the joint.

The next question is whether, when the cartilage is found at operation to be broken, we should remove only the broken portion or the cartilage in its entirety. I think this is the point on which I have heard the greatest diversity of opinion. One group of surgeons is quite definite that in at least some cases it is unnecessary to remove the whole of the cartilage, and they often justify this opinion by saying that they never see those cases again in which a partial removal of the cartilage has been done. There is the other group equally definitely of the opinion that in any lesion of the cartilage the

whole cartilage, and not only the broken portion, should be removed at the time of operation. I am a very firm believer in the necessity of removing all of the offending cartilage. During the past fifteen years I have been obliged to remove many posterior ends of cartilages which have been left at the primary operation.

In regard to after-treatment, my practice is to keep the patient in bed with the knee fixed at an angle of slight flexion for ten days. After this time the stitches are removed and he is allowed to walk about with the leg still fixed on a splint for another ten days, during which time he is persuaded to exercise the quadriceps muscle. The splint is then removed and replaced by a bandage round the joint, and exercises and gentle massage are given to the quadriceps until this group of muscles is equal to those of the other leg. I have never found any difficulty from stiffness following this splint fixation, and I believe it is necessary to allow the wound of the joint to become soundly healed before strain is put on it by flexing the knee.

A CASE OF TYPE IV PNEUMOCOCCAL SEPTICAEMIA

BY

E. A. HOARE, M.R.C.S., L.R.C.P.

The following case may be worthy of record, both on account of its rarity and of its successful conclusion. The diagnosis was only made after many investigations, and the blood culture on which it depends was repeated, at an interval of two days, with the same results.

CASE HISTORY

The patient, a widow aged 34 years, was admitted to hospital complaining of attacks of shivering and pain in the epigastric and lumbar regions for two weeks. There was nothing outstanding in her past history; she had had no serious illnesses, and she had never been abroad. She had no children. As regards her present condition, the pain was not severe and the shivering attacks did not upset her, although they were sometimes followed by vomiting. Her bowels were regular and the motions normal. She had no urinary symptoms, and no menstrual disturbance or vaginal discharge.

Examination of the abdomen elicited slight tenderness and rigidity in the epigastrium and right hypochondrium. There was nothing abnormal palpable. Rectal and vaginal examination revealed no abnormality. Her heart and lungs were normal. Her throat was clean and the teeth healthy. There was no nasal or oral discharge. She was running a swinging temperature from 99° to 104° F., but showed very little general disturbance. The investigations made, the patient's progress, and her treatment can best be considered together, with reference to her temperature charts.

First Week

Pathological investigations revealed a moderately severe anaemia: red cells, 3,600,000 per c.mm.; haemoglobin, 44 per cent. There was a polymorphonuclear leucocytosis of 13,000 per c.mm. Agglutination reactions for *B. typhosus* and *B. paratyphosus* A, B, and C, the Salmonella group, and for *Brucella abortus* were all negative. Urine was normal, except for a trace of bile.

Second Week

An x-ray photograph of the gall-bladder showed no abnormal shadows. On blood culture there was a heavy growth of a short-chain coccus, which was identified as a Type IV pneumococcus. This was repeated two days later, with the same result. The blood sedimentation rate was 50 per cent. (one hour reading). The patient's general condition was worse, although she still felt fairly well. She was given a single intravenous injection of 5 c.cm. of colloidal argentine.

CHART 1.

Third Week

Two injections of 10 c.cm. of Pané's polyvalent anti-pneumococcal serum were given. Although a third blood culture at this time was negative, there was no improvement in the patient's general condition. The blood sedimentation rate had risen to 61 per cent., and the leucocyte count had fallen to 9,000 per c.mm. There was an acute cardiac dilatation, the apex beat being in the mid-axillary line. The patient complained of pain in the right side of her chest, and a small patch of pleurisy and impaired resonance was found. X-ray examination of the chest confirmed the cardiac enlargement, but showed no abnormal shadows in the lungs. A course of injections of S.U.P. 36 and nucleic acid, 1 c.cm. of each daily, was started.

CHART 2.

Fourth Week

For five days the patient had no rigors, but remained very ill. The pulse was persistently over 100, and sometimes up to 140. The anaemia was very severe, the red cells being only 850,000 per c.mm. and haemoglobin 24 per cent.

Fifth Week

A blood transfusion of 750 c.cm. was given, with an immediate improvement in the general condition. In two days the pulse had settled to about 90; although the rigors

CHART 3.

continued they were less distressing, and the temperature was generally lower. The cardiac enlargement began to decrease and the patch in the right lung cleared up.

Sixth Week

The improvement continued, although occasional rigors still occurred. Injections of campolon, 2 c.cm. daily, were started, and also an autogenous vaccine made from the blood cultures by Dr. A. G. Shera. To begin with, 50,000 organisms in 0.1 c.cm. were given, increasing by increments of 50,000 organisms daily. Ten injections in all were administered.

Seventh to Tenth Weeks

The rigors entirely ceased and the temperature remained normal. Three injections of a stronger vaccine, containing 500,000 organisms in 0.1 c.cm., commencing with 0.1 c.cm. and increasing up to 0.3 c.cm., were given. At the end of

CHART 4.

ten weeks the patient was able to be discharged. She had then no abnormal physical signs; she felt well, and was gaining weight. Her red cell count was 4,025,000 per c.mm. and the haemoglobin was 62 per cent.

I am indebted to Mr. A. H. Crook, M.Ch., F.R.C.S., whose case this was, for permission to publish these notes, and to Dr. A. G. Shera for carrying out all the pathological investigations.

Clinical Memoranda

CHRONIC BILATERAL SPONTANEOUS PNEUMOTHORAX

The note by Dr. Joseph Lewis in the *Journal* of October 28th, 1933, on the subject of chronic bilateral spontaneous pneumothorax, emphasizes the necessity for reporting instances of this uncommon condition. The following are records of two cases which have come to my notice. Perhaps the condition is not so rare as its neglect by medical writers would appear to indicate.

Case 1.—A man, aged 46, was admitted to hospital on April 3rd, 1933, complaining of remittent indigestion of eight years' standing and a tender lump in the epigastrium. X-ray examination of the stomach and duodenum, by Dr. Duff Gray, showed no evidence of organic disease. The lump was an epigastric hernia. The patient was somewhat dyspnoeic, and coughed up three to five ounces of frothy sputum in the twenty-four hours. X-ray examination of the chest showed a localized pneumothorax at each apex and fibrosis of both lungs. Tubercle bacilli were not found in the sputum, and several previous searches had also proved negative. The patient had had pneumonia in 1916. A consequent empyema had been "vomited" up without operation. He had been off work for ten weeks, and then in a sanatorium for three months. Neither here nor at the tuberculosis dispensary, which he attended for some years, was any positive evidence of tuberculosis found. In 1919 and 1923 the patient went off work for five and three months respectively after attacks of influenza, and in 1927 he had influenza again. In 1929 he underwent an operation for strangulated hernia. In 1930 he was in bed for one month owing to "congestion of the lungs," and in November, 1932, he was ill for seven weeks with acute bronchitis. He was warned of the danger of recurrence to which his cough

rendered him liable, but in spite of this he insisted on an operation for his epigastric hernia. This was carried out under novocain anaesthesia on May 24th, 1933, and he was discharged on June 21st. He carried on his occupation as a boot repairer until November 14th, when he again sought admission on account of his cough and shortness of breath. An x-ray photograph at this time, seven months after the first, showed the two apical pneumothoraces to be unaltered. The upper edge of the lung was extremely thin, and strands of lung tissue could be seen running towards the parietal pleura (Fig. 1). Lipiodol injection gave no evidence of bronchiectasis. The patient has improved sufficiently to permit him to be discharged from hospital, but his cough and dyspnoea are still present.

FIG. 1

FIG. 2

Case 2.—A man, aged 55, was seen by Dr. Sutherland in January, 1927. He had had pleurisy thirty-five years previously, and repeated attacks in the next few years. In 1923 he had had influenza, and had coughed ever since. There had been slight staining of the sputum once in 1921, and once in 1926. At the time of examination in 1927 the sputum did not contain tubercle bacilli. X-ray examination showed a pneumothorax at each apex, that on the right side being the larger (Fig. 2). There was no evidence of active tuberculous disease, and the case was diagnosed as one of old pleuropneumonia. An x-ray examination by Dr. Twining in 1931, more than four years later, revealed the pneumothorax to be unaltered. A recent attempt to trace the patient has been unsuccessful, so that his present condition cannot be ascertained.

Neither of the cases can be held to come within the category of spontaneous pneumothorax in the apparently healthy; in both there was a long history of antecedent pulmonary disease. Kopstein and Lenz¹ distinguish sharply between benign pneumothorax and that occurring during the course of tuberculosis or chronic emphysema. Neither they nor Kjaergaard, however, regard a past healed tuberculosis as removing the case from the benign class, and Kjaergaard adduces evidence that the mechanism of the "valve vesicle" is operative in the emphysematous patients, as it is in those without previous history of respiratory disease.

That the pneumothoraces were truly chronic in both the cases here reported is indicated by the complete similarity of the x-ray appearances at the beginning and end of the respective intervals. It is necessary to remember, however, that spontaneous pneumothorax may be a recurring condition, and that the symptoms of its onset are sometimes so misleading as to make its discovery a chance one during the course of an x-ray examination. The mere presence of air in the pleural cavity on two successive occasions is not necessarily, therefore, a proof that it has been unabsorbed during the whole of the intervening period.

The second case was brought to my notice by Dr. E. W. Twining, and I am indebted to him and to Dr. D. P. Sutherland, who have placed the radiological and clinical details at my disposal.

Manchester.

Reviews

A SURVEY OF INFLUENZA

Volume ix of the *Annals of the Pickett-Thomson Research Laboratories*¹ is the first instalment of a monograph, in two volumes, devoted to the subject of influenza. It is the work of Drs. D. and R. THOMSON, and forms a valuable addition to the series of monographs already produced by this laboratory. An eminent French physician is reputed to have said that the difference between English and French doctors was that the former were excellent at diagnosis but poor at treatment, whereas the latter excelled in treatment but were indifferent diagnosticians. We should be the last to decry the uses of purely symptomatic treatment, but it is obvious that successful treatment must depend on correct diagnosis, and it is equally obvious, too, that the more we know about influenza the better we shall be able to cope with its ravages. For this reason we owe a debt of gratitude to the authors of this monograph; it should make available much information which otherwise might lie hidden in the voluminous literature of the subject. Their task has been truly herculean, for it has entailed reading and analysing some 4,000 original papers.

The procedure followed is the same as in the previous publications from this laboratory. The literature of each aspect of the subject is reviewed, the authors next add any personal observations which they may have made, and then sum up, giving the conclusions they draw from the available evidence. The present volume covers a large field. It starts with remarks on the nomenclature of influenza, following which are three short sections dealing with the history of this disease and the epidemics caused by it. An interesting account of the epidemiological features of influenza is followed by a consideration of its clinical picture, diagnosis, and prognosis, and then sections on the incidence, mortality, infectivity, relapse rate, and immunity bring us to what is perhaps the most important part of this monograph—that dealing with aetiology. The cynics maintain that in the case of this disease, as in that of the common cold, it is really of little use attempting to discover the causal agent or agents. They argue that if influenza were shown to be due to a variety of primary causal organisms—that is, not a true entity—then this very multiplicity of causation would defeat any specific prophylactic measures. On the other hand, should influenza have a single prime cause, then it follows that an attack of the disease confers little immunity, and so here again nothing could be hoped from specific prophylaxis. This is surely a counsel of despair. When we have solved the aetiological problem of influenza we must be in a better position to deal with it, and it is satisfactory to recall that recent research in this country has gone a long way towards settling this vexed question.

The view that influenza is due to a filterable virus has claimed an increasing number of adherents in the past ten or fifteen years. Though not without some evidence in support of it, convincing proof has been delayed owing to lack of a suitable experimental animal. The investigations of Smith, Andrewes, and Laidlaw, demonstrating the susceptibility of the ferret, has altered all this, and their work has gone far to show the correctness of the filterable virus hypothesis. The authors of this monograph are of a like opinion. They relegate Pfeiffer's bacillus, the various streptococci, and other bacteria encountered in influenza to the status of secondary, but by no means unimportant, invaders. They also give

prominence to the possibility of the filterable virus and one or other of these cultivable bacteria being passed together in nature, each reinforcing the action of the other, and thus giving rise to a more serious type of disease from the start. The beautiful work of Shope on swine influenza lends strong support to such a view, for, in fact, this is exactly what does occur in this disease. It is interesting to note, too, in this respect, that Smith, Andrewes, and Laidlaw have shown that the virus of swine influenza is, if not identical with the human influenza virus, at least a very close relative of it.

The Pickett-Thomson Laboratory is to be congratulated on having given us such a useful monograph—at least, the first volume of it is most satisfactory, and we shall await with interest the publication of the other half.

PRACTICE OF MEDICINE

Dr. F. W. PRICE's *Textbook of the Practice of Medicine*² has now appeared in its fourth edition, some four years having elapsed since its last revision. During that comparatively short period there have been numerous changes in medical outlook consequent upon advances in knowledge and practice, and these are incorporated in the present volume. The most extensive alterations have taken place in the section on diseases of the blood, which has been entirely rewritten by Dr. L. J. Witts, while Lord Horder has rewritten the neighbouring sections on diseases of the lymphatic system and on diseases of the spleen. The former's contribution is an excellent survey of a subject in which he has had considerable first-hand experience, but it must be confessed that the five pages on the lymphatic system and the four on the spleen from Lord Horder's pen are too brief for a work of this nature, and not of the high standard which characterizes this author's work elsewhere in the volume. Other sections which have been very largely revised include those on anoxaemia, alkalaemia, the endocrine glands, digitalis therapy, coronary occlusion, and the treatment of pyelitis. There are over fifty new articles, and almost as many portions of the book contain new material. There do not seem to be very many more pages than in previous editions, but the volume is certainly larger to handle now, though still not unwieldy. The increased bulk appears to be due to the choice of a slightly more opaque paper for the main contents, which is a great improvement. There can no longer be the same criticism, passed on previous volumes, that the print of one page could be seen through the paper from the opposite side. This is still true of the paper in certain sections, where illustrations are present, and the improvement can be easily seen by contrasting pages 981 and 375, for example. The index continues to be of very high standard, running into over 130 pages, and is indicative of the extreme care for detail which the editor has bestowed upon his work. The present edition will be as deservedly popular as its predecessors: a worthy product of the London school of medicine.

RADIOLOGY OF BONES AND JOINTS

Until a comparatively short while ago, the title of Dr. J. F. BRAILSFORD's book *The Radiology of Bones and Joints*³ would have included practically all the clinical uses of Röntgen's discovery. Now, however, so wide has the field become that the diagnosis of thoracic and abdominal disease largely rests upon radiology, and requires special knowledge, experience, and skill, as well

¹ *Annals of the Pickett-Thomson Research Laboratory*. Vol. ix. *Influenza* (Part I). By D. and R. Thomson. London: Baillière, Tindall and Cox. 1933. (Pp. xvi + 640; 28 plates. 42s.)

² *A Textbook of the Practice of Medicine*. Edited by F. W. Price, M.D. Fourth edition. London: H. Millard, Oxford University Press. 1933. (Pp. xiv + 1,995; 106 figures. 36s. net.)

³ *The Radiology of Bones and Joints*. By J. F. Brailsford, M.D. London: J. and A. Churchill. 1934. (30s.)

as special publications. A glance at this volume will show that its 500 pages and 310 illustrations are none too many for the presentation of the radiology of bones and joints.

In his preface Dr. Brailsford rightly lays stress on the value of repeated x-ray examination, for even when a first one has revealed no abnormality a later one may make changes manifest, as in cases of Kümmell's disease. Even in a work of this size it is impossible to represent every known form of abnormality, but this unavoidable lack is largely made up by the copious bibliography, which enables reference to be made to special publications. The author begins with the radiology of the normal skeleton at the time of birth, and discusses the departures from normality which may be found and the conditions which influence the process of ossification. The treatises and textbooks on anatomy of forty years back, and even later, told us authoritatively when and where centres of ossification were to appear, but standard works such as Gray gave little hint as to the researches on which the conclusions were formed. We know now that ossification is often an irregular and uncertain process, for even like twins may show different rates of ossification.

Beginning with the upper extremity, the various sections of the limbs are considered and their abnormalities and dystrophies described and illustrated. Fractures and dislocations of the long bones are but lightly touched upon, because, as the author states, radiographs of them are to be found in most books on surgery. As might be expected, the spine is treated of at considerable length, for this region is one which offers great difficulties to the radiographer and is at the same time liable to many irregularities of development and many injuries which can only be revealed by means of x rays. Such problems are fully discussed by the author. The same remarks apply, *mutatis mutandis*, to the chapters on the head. The reproductions of radiographs and the diagrams are clear and informative.

THE PINEAL BODY

Dr. JEAN CALVET's monograph *L'Épiphysse*¹ will attract those who are interested in the method of applying comparative anatomy and embryology to the elucidation of disease. There have been three stages in our conception of the pineal body. In the first, purely speculative stage, psychical functions were attributed to it; in the second, the researches of Baldwin Spencer and others revealed that it contained a vestigial eye, which atrophied in the higher vertebrates, and attention was concentrated on it as a key to the origin of vertebrates from invertebrates, particularly by Gaskell. In the third phase the association of disorders of this gland with macro-genitosoma led to its being regarded more as an endocrine organ, although no hormone has ever been extracted from it. Indeed, the suggestion has been made that its influence on the endocrine system is through the nervous system rather than by chemical means, a suggestion which recent work on the close association between the diencephalon and the endocrine glands renders all the more plausible.

Dr. Calvet's view is that, like the pituitary and the adrenal, the pineal has a double origin—one parietal, which is the vestigial eye, the other, the true epiphysis, which is neuroglandular, analogous to the post-pituitary, and similar in histological structure. He regards it as an endocrine organ with a special influence on growth and gonadal development, and supports this thesis by an experimental and clinical study.

PHYSIOLOGY OF MUSCULAR ACTIVITY

Increasing stress is being laid on the importance of exercise to the citizen in every branch of life. The Board of Education is taking great interest in the physical training of children, and a number of students are now approaching the subject of physiology from the special point of view of exercise and the function of the muscles. For these Dr. E. C. SCHNEIDER's work² will prove a useful handbook. He takes muscle as the key to physiology, and shows how, for adequate understanding of the contraction of any one muscle fibre, it is necessary to understand the working of the whole body. After a review of the structure of muscle and of present theories of muscle contraction, he goes on to survey the fuel used and the way in which it is brought to the muscle, and the role of oxygen in physical exercise. This leads him to a study of respiration and the circulation, and this in turn to blood pressure and the co-ordination of all these activities. He thus produces what is in fact a little textbook of physiology, written from his specialized point of view. Concluding chapters deal with tests of physical fitness and the effects of physical exercise at high altitudes and in different temperatures. Dr. Schneider attempts to frame a definition of the term "physical fitness," but like many other experts is unable to tie this elusive concept down to any rigid words. He reviews tests from all over the world, including our own Royal Air Force efficiency tests, and draws attention to the discrepancies which are often found between athletic prowess and physiological findings. The book is illustrated with tables and some outline sketches, and is supplied with a very full bibliography. The index appears to have a very high proportion of proper names to its other entries, showing that the author has consulted authorities from all countries.

TORTURE IN ENGLAND

The law and practice of torture in England are recorded and expounded by Dr. L. A. PARRY in his book entitled *The History of Torture in England*.³ He gives his readers a rapid and interesting review of the subject and, in spite of the title, includes chapters on torture in Scotland and in Ireland. The latter of these chapters is quite short, and one wonders whether it is accidental or significant and characteristic that "Ireland was comparatively unaffected by the torturers. The custom was recognized neither by Common nor Statute Law, and only a few cases are recorded in this country." Dr. Parry's volume is in the nature of a compilation rather than the result of any profound research, but it is obviously the outcome of a good deal of reading, and has been put together with considerable care and judgement. It happily does not purport to be a complete record even of sample cruelties, but it illustrates the circumstances in which and the ways in which the practice of torture and brutality was followed, especially under the Tudors and Stuarts, both in the punishment of malefactors and as a means of extracting confessions and depositions from innocent and unwilling witnesses or victims, in spite of the fact that it was forbidden by Common Law, at least since the time of Magna Charta. The Courts of Star Chamber and High Commission, through the instrumentality of which the attempt was made to substitute for the Common Law the will of the sovereign, are described, and characteristic instances of their action are narrated: brutal punishments

² *Physiology of Muscular Activity*. By E. C. Schneider, Ph.D. D.Sc. London and Philadelphia: W. B. Saunders Company. 1933. (Pp. 401; illustrated. 14s. net.)

³ *The History of Torture in England*. By L. A. Parry, M.D. B.S., F.R.C.S. London: Sampson Low, Marston and Co. Ltd. 1934. (Pp. viii + 244. 10s. 6d. net.)

imposed both by them, and later by the ordinary courts, are described, and there are notes on trial by battle, the "peine forte et dure," and allied proceedings. There are also chapters on witchcraft and the Church in relation to cruelty, and, in conclusion, accounts are given of several important trials relevant to the subject. The book can be commended to the curious as a guide to a not unimportant byway of history.

Notes on Books

We welcome a fifth edition of Dr. JOSLIN's *Diabetic Manual*,⁷ so well known throughout the world. The depreciation of the dollar now, fortunately, brings it within the means of many more persons in this country. No essential change in the aims and scope of the book is introduced, and it still remains a straightforward guide for the diabetic on what he ought to know to maintain normal health by diet and insulin. Its interest and liveliness, however, are greatly enhanced by attractive new illustrations. We are glad to see that the chapter of Socratic questions and answers is retained, for it ensures that no patient can escape essential knowledge required for his well-being. Altogether the book remains a living testimony to the clinical greatness, powers, and humanity of its author. From the practitioner's point of view it is hardly dogmatic enough to enable him to treat a case without the master's guiding hand.

In *A German Reader for Biology Students*⁸ the authors have brought together a series of short passages from German scientific publications, graded in order of difficulty, and supplemented by a full vocabulary. The book is a sequel to *The First German Course for Scientific Students*, and can be commended to those who wish to acquaint themselves with modern German scientific phraseology. Grammar explanations are excluded, having been dealt with in the earlier volume, but useful hints are to be found in the vocabulary, which will be adequate for those who already have some knowledge of German.

A little volume by Dr. LARTSCHNEIDER⁹ is the first instalment of a work which is intended to revolutionize our conceptions of embryology and of cellular pathology. The first part sets out to correct our views of the histogenesis of epithelium and of the aetiology of cancer. The author's conclusions are not based on new methods of investigation or original preparations, but are derived from histological preparations of other authors, some of which are reproduced in the volume, and to which the author applies a different interpretation. The ambitious attempt fails to convince, yet one cannot but admire Dr. Lartschneider's courage and seriousness.

A comprehensive and practical *Handbook for Health Visitors in India*¹⁰ has been compiled by Dr. RUTH YOUNG, who is secretary of the Lady Reading Health School at Delhi, and director of the Maternity and Child Welfare Bureau of the Indian Red Cross Society. It contains an orderly and well-set-out compendium of information about the infant and young child in health and disease, and indicates the right lines to be taken in the many bewildering situations in which health visitors in India may find themselves plunged. The various topics are dealt with clearly as well as interestingly, and the author's fifteen years of practical experience of training health visitors have enabled her to produce a book which will

be useful to students and practitioners of preventive nursing in the Tropics generally, as well as in India.

The novel of *Damaged Lives*,¹¹ adapted by C. J. Eustace from the film by Don Davis and Edgar G. Ulmer, like Brieux's well-known play, is a serious piece of propaganda to inculcate the dangers of alcoholic indulgence, pre-matrimonial sexual intercourse, and resort to quacks with consequent neglect of proper treatment. The work is introduced by Mrs. Neville Rolfe, Secretary-General of the British Social Hygiene Council, and the composition, aims, and objects of that Council are appended to the story.

For the eighth year Dr. A. RAVINA has produced his brief annual review of the therapeutic procedures, new medicaments, and apparatus under the title *L'Année Thérapeutique*.¹² Among the sections which may be noted is a good one on the use of evipan for general anaesthesia, an interesting account of irradiation of the carotid sinus as a means of treatment in vascular hypertension, and the somewhat amusing suggestion of using raw onion for the treatment of erythraemia.

In his little book entitled "Organization of the Medicine of the Future,"¹³ which consists of a communication read before the First Congress of Compulsory Insurance at Santiago, Dr. GARCIA TELLO advocates the formation of an office of compulsory national insurance, the creation of a tribunal for medico-social offences, curative and preventive vaccination whenever possible, the destruction of animal carriers and isolation of human carriers. The principal diseases against which an active campaign should be carried out, in the author's opinion, are tuberculosis, syphilis, oral sepsis, and cancer.

Fluorescence Analysis in Ultra-Violet Light,¹⁴ by J. A. RADLEY, describes the uses of ultra-violet light in the detection of substances through the quality of the fluorescence which they individually exhibit when thus illuminated. This method of examination can be usefully employed in a great variety of investigations. Quinine is detectable in human milk in an attenuation of about one part in ten million parts. Bacteria show distinctive kinds of fluorescence. Pigments, dyes, and inks which appear alike to unaided vision are distinguished when illuminated with ultra-violet rays. Counterfeit stamps and documents can thus be often detected. Traces of obliterated writing are also rendered visible, and geological specimens are caused to exhibit details of structure which are not otherwise evident. General use has been made of the rays in the comparison of specimens of drugs, foods, and technical materials. The book describes the apparatus available for production of the illumination and the accessory apparatus by which colours may be compared and photographs obtained. It also gives much useful information, derived from the experience of workers in many fields, about the application of ultra-violet radiation, and furnishes a remarkably large number of bibliographical references useful to workers in this branch of analytical investigation.

The total number of names in the *Dentists Register*¹⁵ for 1934 is 14,425, being 103 less than the figure for the preceding year. Of these, 7,606 (52.73 per cent.) are registered with medical, surgical, or dental qualifications, as compared with 7,500 in 1933. Only five out of the 233 persons newly registered are without qualifications. Death and other causes were concerned in the removal of 652 names, while 253 which had been omitted from previous editions for various reasons now appear.

FLESH FOODS AND THEIR LOSSES ON COOKING

AN ANALYTICAL STUDY

The chemistry of food is a field of inquiry which has been remarkably developed during the current century. Our knowledge of the accessory factors, starting from zero about 1912, has already attained to a high degree of refinement, and fruitful attention has been focused also upon the role of the mineral constituents. Older lines of study into the protein, fat, and carbohydrate content of foodstuffs, begun prior to this active period, have been continued, but most of the food tables evolved as a result have been open to criticism on the ground that they relate to raw materials only and take no account of the effects of cooking. This is a practical objection, because doctors in ordering diets for patients have to reckon, as a rule, in terms of the cooked article. In order to fill this gap in our information the Medical Research Council made grants to Dr. R. A. McCance, aided by Mr. H. L. Shipp, to carry out systematic analyses of cooked flesh foods.

The report of these observers,¹ after describing their analytical methods, proceeds in its principal section to deal with British flesh foods, including fish, in the cooked state. The figures are set forth in eight tables for fresh fish, preserved fish, shell-fish, fresh meat, preserved meat, poultry and game, organs, and a few raw foods, showing for each class the total, purine and non-purine nitrogen, protein, fat, carbohydrate, and specified metals, etc., present per 100 grams. The authors confirm the low values found by others for calcium in beef and mutton and its higher range for fish. They regard fish like sardines, sprats, and whitebait, which have fine edible bones, as valuable sources of this mineral, and bring out that the same three kinds contain more iron than cooked halibut, plaice, or trout.

Studying the losses brought about by cooking, the authors observe that from the death of the meat animal till the flesh is eaten loss takes place at every stage. Not only must the skin, head, and bones be rejected as nutritionally valueless, but the heat of cooking comes creeping in to diminish the substance of what remains.

LIEBIG'S DOCTRINE

According to Liebig's doctrine the fine art of cooking lay in producing at once upon the surface of meat a pellicle, seal, or coagulum which would serve to keep in its goodness. In order to form the pellicle, meat for boiling must be plunged at the outset of the cooking into boiling water. If, on the contrary, the meat at the beginning were immersed in cold water, which was then gradually raised to the boiling point, all its virtues of protein and the rest would dissolve out and be lost in the water round it before the saving pellicle could be formed and brought into action. Subject to the different conditions of cooking, the same principle was held to apply to roasting, grilling, and frying. This doctrine, accepted by scientists of standing without apparently much investigation, came to be widely credited by the public, although the work of American observers in 1901 and later lent it little countenance.

Liebig's hypothesis was put to the test by the authors of the report under notice. They cooked two lots of meat in two different ways, starting one lot in boiling water, and the other lot in cold water which they slowly heated. When cooking was complete, comparison showed that the ultimate losses of water, salts, and weight were precisely the same in the two cases. Moreover, during the first hundred minutes all losses were greater in the meat which had been started at boiling temperature. There was no

action which could be ascribed to the existence of a retaining pellicle.

It was noted, too, that when a salt beef round, weighing 3,850 grams, was placed in boiling water it took one and a half hours for a thermometer in the centre of the joint to reach 49° C., while three hours elapsed before 90° C. was registered. This observation confirmed the general view that meat is an inactive conductor of heat, and suggested that there could be no convection currents through its substance.

LOSS OF WEIGHT AND VOLUME

It is the rule that meat, when heated in cooking, loses weight and volume. The application of heat over 60° C. to beef, fish, and flesh foods leads to the shrinkage of their proteins and the expression of juices. This is the only cause of salt loss when meat is roasted or steamed, but in boiling there is further loss of salts by leach into the surrounding water. Raising the temperature accelerates the rate of shrinkage, but does not greatly affect the final result. Egg proteins did not shrink at all when heated up to 100° C. The shrinkage of beef, after steaming for forty-five minutes, was represented by a loss of weight of 42 per cent.

All methods of cooking that are attended with evaporation tend to conserve the salts and extractives of the meat. Roasting, grilling, and, above all, frying have been found to lead to smaller salt losses than steaming or boiling. The reason is that in roasting, grilling, and frying, when shrinkage occurs and the juices are expressed, the water evaporates, leaving the salts on the surface of the meat. If, however, the roasting takes place in a pressure cooker or an electric oven, evaporation is checked and the dripping juices carry the salts away. The juicy appearance of electrically roasted meat is superficial and fallacious, being due merely to lack of active evaporation in the electric oven. Gas ovens are better in this particular than those heated by electricity.

POPULAR ERRORS

As already noted, the authors have exposed the error that a pellicle forms when the cooking of meat commences at a high temperature. They consider that unless the procedure can be defended on the ground of flavour or easier digestion there is no point in making the water boil before the meat is immersed or in heating up the oven before the joint is put in. Further, they traverse the common belief, which, "apart from dyspepsia, is probably psychological in origin," that underdone meat is more nutritious than meat that has been overcooked. Since the greater part of the weight lost during cooking consists of water, it is obvious in their view that, pound for pound, overcooked meat must contain more protein, and probably more fat, than undercooked meat, and be therefore a more concentrated food. As regards the saline content, if the piece of meat is small and boiling prolonged, its salts will leach out freely into the water, so that its salt percentage is lowered. If the piece is large, salt and water will be expressed in nearly equal proportions, and salt concentration in the meat will be about the same whether it is undercooked or overcooked. If it is a case of roasting, since water is being continuously lost through evaporation, the longer the process of cooking continues the higher the percentage of salts in the meat will tend to rise.

On the scientific side the special value of the report will probably be adjudged to lie in its less spectacular tabular portion, which is a course added to the foundations of nutrition. On the more domestic side it will be of interest to all, and no doubt intriguing to many, for its disclosure of the results of the application of heat in cooking and its disturbing discriminations against some familiar views and methods. The exemplary graphs in which the work abounds will be appreciated by all its readers.

¹ Medical Research Council, Special Report Series, No 187. *The Chemistry of Flesh Foods and their Losses on Cooking*. By R. A. McCance, M.D., Ph.D., M.R.C.P., and H. L. Shipp, B.Sc., A.I.C. London: H.M. Stationery Office. 1933 (2s. 6d. net.)

British Medical Journal

SATURDAY, APRIL 21st, 1934

WHAT CAUSES PEPTIC ULCER?

A bewildering variety of quite unrelated causes have been suggested to explain peptic ulceration. Almost every process has been invoked which is known to be the basis of morbid changes elsewhere, including infection, interference with blood supply, trauma, allergy, vitamin deficiency, and disturbances of endocrine function. In so far as these hypotheses are based on experimental evidence, their weakness lies in the fact that the type of ulcer produced has usually been acute, superficial, and rapidly healing, whereas we are more concerned to ascertain the aetiological basis of a type of ulceration having as essential features deep destruction and a most persistent chronicity. Ulcers described as possessing these characters have, however, been produced experimentally, and the body of similar evidence accumulated since the original experiments of Mann and Williamson¹ is certainly the most serious factor which has to be reckoned with in formulating conclusions on this subject at the present time. These workers argue that peptic ulceration occurs only in areas of mucosa exposed to the action of acid gastric secretion, and their experiments consist in inducing persistent ulceration beyond the pylorus by diverting the alkaline secretions which normally neutralize the gastric contents at this point. These secretions are the bile, the pancreatic juice, and the secretion of the duodenal mucosa, and several ingenious proceedings by which these were diverted to a lower point in the small intestine all had the same effect on that portion of the bowel which was left in the position of the duodenum but was deprived of its natural secretory defences.

That the duodenal mucosa itself takes an important share in neutralizing acid from the stomach is shown by the work of Florey and Harding,² who were able to obtain its secretion in considerable quantities from tied loops of duodenum in the rabbit, and found that it possessed a high bicarbonate content. They propose tentatively that an insufficiency of this secretion may be a factor in producing peptic ulceration: the case for this hypothesis would be stronger if atrophic changes in Brunner's glands, which produce this secretion, were to be demonstrated in cases of peptic ulcer. That the action of the gastric juice is responsible for peptic ulceration is also suggested by a variety of experiments performed by Matthews and Dragstedt.³ They separated portions of stomach to make an independent sac, in which ulcers formed and even perforated, owing, it is assumed, to the unaided and unrelieved effect of

the contained secretion; or attached the separated portion to the small intestine, in which ulcers were produced with a frequency which increased with the distance of the point of attachment from the stomach. This last observation suggests that a degree of resistance to the action of gastric juice exists at various levels in the upper alimentary tract proportionate to their degree of normal exposure to it. Taken as a whole, all these experiments, among which those of Mann and Williamson at least have been repeatedly confirmed, point to the local action of gastric secretion as the chief factor in maintaining peptic ulceration, and the consistent finding of hyperchlorhydria in the subjects of this disease supports the same conclusion.

It is therefore a little surprising to find it seriously suggested that peptic ulcer is due to a specific infection. Saunders, Holsinger, and Cooper,⁴ in a recent publication reiterate the original findings of Saunders⁵ to the effect that a constant and distinct type of streptococcus can be cultivated from peptic ulcers, and adduce evidence that feeding cultures of this streptococcus to dogs subjected to one of the surgical procedures devised by Mann and Williamson increases the subsequent incidence of ulceration and alters its type. The original evidence in favour of this streptococcus as a cause of peptic ulcer included its constant appearance in cultures made from ulcer tissue, the morphological and serological homogeneity of the strains so isolated, and the presence of agglutinins for it in the blood of patients suffering from peptic ulcer. One objection to it is the purely arbitrary method of culture employed. Why, for instance, should a streptococcus which happens to grow in the depths of "semi-solid hormone agar" inoculated with material containing a mixture of bacteria (such, even, as a loopful of pyorrhoëa pus) be the one micro-organism that matters in that material? It is arguable that this streptococcus grows constantly only because the conditions afforded for it happen to be more favourable than for other equally indifferent bacteria in the inoculum; it is also more than probable that if a certain streptococcus is constantly present in ulcerated stomachs it is only there because it is a type possessing greater resistance to acid than others among the numerous mouth streptococci normally swallowed in hundreds of millions every hour. It is not inconceivable that such a streptococcus may multiply in the base of a preformed ulcer and even give rise to agglutinin formation, but that is not to say that it produced the ulcer. There are endless gaps and possible fallacies in this work: it is, in fact, a good example of the pitfalls which beset those who imagine that to find the cause of a lesion one has only to look for a germ in it. Anyone with suspicions that Saunders's conclusions are possibly valid should read the paper⁶ in which he claims to have isolated forty-one strains of streptococci "proved identical" by various serological methods from gastric ulcer, ulcerative colitis, carcinoma of the rectum, the cervix uteri, and carcinoma

of the breast: it is seriously suggested that this streptococcus, which is also found in cow's milk, plays a part, the nature of which is postulated in specific terms, in producing cancer. Such streptococci, like diphtheroids, are best avoided by investigators with their ultimate reputations at heart.

A BUDGET OF RELIEF

Mr. Chamberlain's observation that we have now finished the story of *Bleak House* and are starting the first chapter of *Great Expectations* hits off the situation neatly, and the emergence from the danger of financial disaster to comparative safety is summed up in his remark that the realized surplus of last year almost exactly balances the deficit of the year before. The Government can congratulate the whole body of taxpayers, and deserves their congratulations in return, on this result: there is probably no other country in the world which would have made the same sacrifices, and certainly none which would have shown the same cheerfulness and fortitude in the task. The Chancellor rightly emphasized the unique position of the British Empire in national finance as compared with the present tribulations of the Exchequers of other nations. The world-wide falling off in international trade has affected the industries and finances of every country, and the United Kingdom, with its dependence on foreign sources of food and raw materials and the traditional importance of its mercantile marine, has felt the depression as acutely as any other nation. For three years steady and varied efforts have been made to encourage trade in the internal market; the effects are now becoming apparent, and the contraction of foreign is being offset by the expansion of home trade. The result on the national finances has been most encouraging not merely in its direct effects but also as showing that, if the barometer of British trade is still a long way from "set fair," it is at least rising steadily.

A few weeks ago the newspapers generally were indulging in estimates of the disposable surplus for the current year, which have proved too sanguine—estimates of £45,000,000 and upwards were not uncommon, whereas the actual figure is about two-thirds of that amount, which, as Mr. Chamberlain very rightly said, is "if not dazzling at any rate a very substantial surplus." It is probable that in making his calculations the Chancellor has been deliberately cautious. The worst that could happen after the encouragement of the surplus of last year and the fiscal reliefs now granted to taxpayers generally would be for the country to have to face another deficit, however small, in twelve months' time. Nationally it would be deplorable; politically it would be disastrous. Criticism of expert Treasury estimates is a fruitless exercise of the wits for anyone without the special means of information necessary for the task, but on general grounds there seems good reason to hope for a surplus at the end of the present year, though no doubt it will be of more modest dimensions. Mr. Chamberlain laid some

emphasis on the fact that improvements in trade are not immediately fruitful so far as the Treasury is concerned, at least in the important spheres of income tax, surtax, and estate duty. While, therefore, no increased yield—apart from the receipt of the £12,000,000 lost last year by postponement of part of the January instalment—can be expected from these taxes in the coming year, there should be enough gain in the future to provide further relief for the taxpayer.

Few will be found to cavil seriously at the Chancellor's distribution of relief among the many classes of deserving citizens. Two-thirds of the surplus is absorbed by the reduction of the standard rate of income tax from 5s. to 4s. 6d. The effect of that is, of course, to reduce each taxpayer's contribution by 10 per cent., whereas an increase in the scale of allowances would give a larger relative advantage to the smaller taxpayers. Of all existing taxes income tax is probably most acutely felt, and a standard rate of 5s. is almost impossible to justify in time of peace. Indeed, having regard to the reduced scale of personal allowances now in force it is fairly comparable in weight to the 6s. tax which was the maximum rate in force soon after the war. It is to be hoped that next year the allowances can be materially increased. One of the chief necessities of the present time is for a stimulated demand for ordinary commodities and services, and a reduction in the tax paid by the ordinary citizen would operate in that direction as effectively as, if not more effectively than, an equal diminution in the amounts paid by the large companies and financial concerns who are chiefly affected by the reduction in the standard rate from 5s. to 4s. 6d. At the same time, the psychological effect of that reduction will be of the utmost benefit to trade generally, and we agree that the Chancellor's decision is the right one, but only on the assumption that next year he can at least go some way towards restoring the pre-1931 scale of allowances. Turning to smaller, though not less important, allotments of relief, the restoration of the full unemployment benefits as from July 1st, and of one-half of the special "cuts" inflicted on certain groups of public servants—including insurance doctors and pharmacists—will meet with general approval, the more so as the cost of the former will prove less than at one time seemed probable owing to the absorption of out-of-work operatives by the improvement in trade generally. The reduction in the horse-power tax on cars as from January 1st had not been generally anticipated, and is a minor but welcome advantage to medical practitioners.

It is often said that there is no such thing as gratitude in politics. Perusal of the general press in the past few days apparently gives the lie to the statement, though the gratitude may not prove very durable and may consist largely of a hope of favours to come. If the latter consideration enters rather largely into the national feeling Mr. Chamberlain is partly responsible. He has shown himself to be a prudent and courageous Chancellor, and his tone of cautious but confident optimism gives good ground for thinking that in his

case promise will be outrun by performance. A few months ago the country was watching the rising tide of Exchequer receipts with keen interest and increasing hope. The Budget statement has set bounds to extravagant expectations that were voiced in some quarters, but at the same time it has satisfied the more modest hopes and kept others alive for future satisfaction.

THE ANNUAL REPORT OF COUNCIL

Almost the whole of this week's *Supplement* of fifty-two pages is given up to the Annual Report of Council for 1933-4. The detailed financial statement will appear next week, and the Supplementary Report of Council on June 23rd. These three documents, with amendments and riders to come from the Divisions and Branches, make up together the material for discussion and decision at the Annual Representative Meeting which opens at Bournemouth on July 20th. Even a casual glance through the main report published to-day must bring to the mind some idea of the multifarious activities of the world-wide organization which is known everywhere, to doctors and laymen alike, as the B.M.A. It is in part a record of work done. Thus, for example, the Arthritis Committee, the Nutrition Committee, and the Committee on Medical Education have completed the tasks set them, and their findings are before the profession. It is in part also a survey of work, already begun or planned, of which the main burden must be taken up during the next twelve months. The field covered by the report includes, directly or indirectly, every department of professional life—science, clinical medicine, public health, medical economics. We venture to say that it is the duty of every one of the 35,000 members of the British Medical Association—no matter where he lives or what his branch of practice—to look carefully through the *Supplement* this week and make himself acquainted with its contents. Thereafter, if he feels disposed to criticize it in detail, so much the better for him and for the Association.

GERMAN CARDIOVASCULAR RESEARCH

The recent publication of the annual proceedings of the German Society for Cardiovascular Research¹ is of importance in that it contains contributions from some of the pioneers of modern work and also much suggestive matter for future work. In a masterly article Professor H. E. Hering deals with the reflex nervous control of the circulation (die Blutdruckzügler), and among other things shows that the significance of the carotid sinus nerves and the aortic nerves must be extended to include reflex control of vaso-dilator tone, of the tone of the cardio-inhibitory nerves, of tonic inhibition of vaso-constrictor tone, of parasympathetic tone, and of tonic inhibition of the accelerators. Stöhr of Bonn gives some interesting histological evidence of the nerve supply of vessels and puts forward the view that every cell of the entire vascular system is under nervous control. Koch of Bad Nauheim discusses the relative importance of the sympathetic and parasympathetic in the control of the heart and of the vessels: he shows that for the heart the parasympathetic

normally preponderates, while for the vessels the sympathetic exerts the greater influence. Using Rijlant's cathode-ray oscillograph, Karásek presents results on the rabbit's depressor nerve which show that normally the depressor is in a state of continuous excitation, and that in hypertension its activity increases, and in hypotension it diminishes. Bohn of Frankfurt reviews shortly his important experiments which, it is claimed, demonstrate the presence of a circulating pressor substance in secondary hypertension (pallid type). A similar pressor substance can also be shown to exist in the blood of "plethoric" hypertensives, but not to nearly the same extent. In both types pressor substances can be shown to exist in the urine: in the cerebro-spinal fluid the results were confusing, since even when strong pressor activity could be obtained from the blood the cerebro-spinal fluid might be quite inactive. Again, in the urine anti-diuretic substances could be demonstrated in all types of cases, even in normal individuals, which rather militates against the pituitary hypothesis. Many other interesting papers appear in these proceedings which are well worth studying.

SAFE MILK IN CANADA

It is symptomatic of the increasing recognition of the part played by milk in carrying disease that the *Canadian Public Health Journal* has devoted its entire January number to "Safe Milk." There are altogether seventeen papers, mostly by different authors, dealing with this subject from various aspects. Dr. Gwatkin discusses contagious abortion in cattle, and mentions that 52 out of 102 cows showing a serum agglutination titre of 1 in 100 or over were actually excreting *Br. abortus* in the milk. Laboratory tests showed that strains of this organism were destroyed by exposure to a temperature of 140° F. for ten to fifteen minutes. Dr. McNabb states that during the five years 1929-33 no fewer than 480 cases of undulant fever have been diagnosed in Ontario alone. It is interesting to note that of 7,379 Widal sera tested, 836 agglutinated *Bact. typhosum*, 325 *Bact. paratyphosum* B, and 289 *Br. abortus*. The total proportion, therefore, of sera agglutinating organisms of the enteric group was 19.6 per cent., and *Br. abortus* 3.9 per cent. These figures closely resemble those for England and Wales—namely, 21 per cent. and 3.5 per cent. Dr. Marguerite Price has continued her investigation in Toronto of non-pulmonary tuberculosis of bovine origin in children. She has now examined 300 patients under 14 years of age, and found forty-five of them to be infected with the bovine type of bacillus. All the patients infected with the bovine type had consumed raw milk and had come from districts outside Toronto. In Toronto itself, where 99.8 per cent. of the milk is pasteurized, not a single case of bovine tuberculous infection has been detected. Examination of 100 samples of pooled raw milk before pasteurization revealed tubercle bacilli in twenty-six. After the same milk had been pasteurized, not a single sample was shown to be infected with tubercle bacilli by the guinea-pig test. This investigation is unique, and constitutes the strongest and most direct evidence of the importance of milk in causing tuberculosis that has ever been forthcoming. Dr. Murray presents figures of epidemic milk-borne infection in Canada, but is careful

¹ *Verhandlung der deutschen Gesellschaft für Kreislaufforschung. VI. Tagung 1933. Herausgegeben von Professor Bruno Kisch. Dresden: T. Steinkopff. (RM.15.)*

to point out that they refer only to those epidemics which were brought to the attention of the provincial authorities or the local authorities of the twenty-four largest cities, and in which the milk supply was proved definitely to be incriminated. During the fourteen years 1920-33 there were thirty-one outbreaks of typhoid fever with 6,336 cases and 662 deaths, three outbreaks of paratyphoid fever with 522 cases and three deaths, five outbreaks of scarlet fever with 106 cases and no deaths, and three outbreaks of septic sore throat with 584 cases and four deaths. The same author reports on the extent of pasteurization in Canada. In nineteen of the twenty-four larger cities an average of 60 per cent., and in the remaining five cities 100 per cent., is pasteurized. There are now twenty-five municipalities in which compulsory pasteurization of all milk is required. In view of the importance of efficient pasteurization, Dr. Berry's article on common defects in pasteurizing plants is most valuable, and should be studied by all who are responsible for the supervision of pasteurization. Dr. McKay reports an outbreak of septic sore throat due to milk that had been imperfectly pasteurized, and indicates how it could have been obviated by adequate instruction of the dairyman. Other articles deal with model milk by-laws, clean bottles, sanitary caps for milk bottles, pasteurizing equipment for small dairies, certification of operators in pasteurizing depots, home pasteurization of milk, dairy farm inspection, and the nutritional value of pasteurized milk.

AIR CONDITIONING FOR ASTHMA AND HAY FEVER

The work of the late Dr. Storm van Leeuwen in treating hay fever and asthma patients in a protected atmosphere is well known. His researches have been carried a stage further by Dr. L. M. Gay at the Johns Hopkins Hospital, in conjunction with the research department of the Frigidaire Corporation, who manufacture apparatus by which the air in a room can be kept at a constant temperature and humidity and thoroughly cleaned of all impurities. A room large enough to accommodate four bed-patients was equipped with an air-conditioning unit. The windows and door were kept closed but not sealed. The humidity was maintained at 40 per cent., as against an outside humidity in August and September of 80 to 90 per cent. The temperature was maintained at 10° below that of the outside air. Tests with oiled slides showed that although much pollen was present in the outside air none reached the room. Patients with hay fever uncomplicated by asthma improved strikingly in ten or fifteen minutes: within an hour the symptoms had gone. Patients with asthma as well as hay fever did not respond quite so rapidly, although within an hour there was a great improvement in their general condition. The symptoms soon returned when the patients left the room, but if they were allowed to remain in it long enough they suffered less irritation afterwards from the outside air. The air conditioning appeared to give patients a rest period during which they could build up resistance to the ordinary atmosphere. Some earlier experiments by Dr. Isobel Beck¹ with a filtered atmo-

sphere showed that patients who spent a considerable amount of time and slept in the pure atmosphere gained a large measure of permanent relief. The experiments at the Johns Hopkins Hospital were not continued long enough to demonstrate the full benefit of the protection of an air-conditioned atmosphere, but they served to indicate that air conditioning is a powerful adjunct to other remedies for all respiratory disorders in which atmospheric conditions are a contributory factor. Drs. T. A. and W. H. Taylor,² in a recent article, describe an ingenious apparatus for conditioning the air in a bed tent and for supplying an atmosphere rich in oxygen. This might prove of use in cases of acute pneumonia. Experiments on the treatment of, for example, bronchitis ought to yield some interesting data.

INVESTIGATION OF PUERPERAL SEPSIS

In a recent circular to medical officers of health the Chief Medical Officer of the Ministry of Health states that the arrangements entered into by the Departmental Committee on Maternal Mortality for bacteriological investigations at a central laboratory of cases of puerperal sepsis have been discontinued. It is hoped, however, Sir George Newman continues, that medical officers of health will take every opportunity of obtaining assistance from bacteriologists attached to adequately equipped local laboratories in investigating pyrexia in lying-in women. He recommends that isolation and separate nursing of the patient should be immediately arranged, and that swabs be taken from the cervix, the throat, and the nose, while search for septic foci should be made in persons in contact with the patient during labour and in the subsequent forty-eight hours. "It should be remembered," he adds, "that as contact with hands and instruments is the most likely mode of infection of the genital tract, particular attention should be directed to infections or abrasions of the skin in anyone who has had such contact with the patient." The assistance of the Ministry will continue to be available to all medical officers of health desiring help in dealing with cases of puerperal infection.

NERVE GRAFTING FOR FACIAL PARALYSIS

After the meeting of the Council of the Royal College of Surgeons of England on April 12th Mr. V. E. Negus gave a demonstration to the Council of a film illustrating ciliary activity and the action of various drugs on ciliary motion. A film illustrating the results of nerve grafting for the relief of facial paralysis as carried out by Dr. A. B. Duel of New York was also shown. The method which was adopted for the treatment of these cases was the result of a long series of experiments carried out by Dr. Duel and Sir Charles Ballance in London and New York. The method consists in preparing a small peripheral nerve by section *in situ* ten to twenty-one days before the operation of repair. The prepared nerve is implanted in the Fallopian canal without sutures and covered with gold foil. The interesting feature of this work is the rapidity with which the recovery takes place, even in cases where the facial paralysis has existed for some time. The

¹ *Med. Journ. and Record*, August 3rd, 1932

² *Anesthesia and Analgesia*, 1934 (January-February), xiii, 22.

justification for operation in long-standing cases of facial palsy depends on whether the muscles of the face respond to the galvanic current. In almost all cases operation should not be delayed; the prepared graft operation on decompression should be performed. The results of using prepared grafts show that return of faradic response in the palsied muscles takes place in less than half the time that is required when a fresh nerve graft is employed. The degenerated nerve graft consists of a series of tufts through which the axis cylinders of the central nerve segment slide along, pushing aside the lipid contents. Sir Charles Ballance left America eighteen months ago, and as there are no baboons at the Royal College of Surgeons he has not been able to continue the research on the lines he and Dr. Duel were engaged in for some years. Dr. Duel, however, has been continuing the research with great enthusiasm, employing for this purpose a large number of monkeys: and, moreover, he has applied the new method with great success to a large number of patients suffering from facial palsy. In cases of Bell's palsy Dr. Duel has operated on many patients, decompressing the inflamed and swollen nerve in the aqueduct by removing the outer bony boundary of the canal and slitting up the fibrous sheath. In some of these patients Sir Charles Ballance was present at the operation, and in many others previously operated on he has observed the great success of the operations. The method of anastomosing the facial nerve to another nerve in the neck is definitely abandoned for the procedure of exposing the nerve in the canal, excising the diseased or damaged portion, and replacing in the gap so formed a prepared graft.

WHEN HOSPITALS ADVERTISE

Time was (writes a correspondent) when the display to the general public of objects illustrating morbid anatomy would have been received with real or pretended horror. The new generation is less squeamish. Just now the world and his sweetheart, wandering up and down the corridors of the "Ideal Home" Exhibition at Olympia, stop with undisguised interest at the hospital stands where jars containing pathological specimens and other unlovely things are on view. When the exhibitor at the St. Bartholomew's Hospital stand holds up a jar which he says contains an entire varicose vein, or an enlarged heart, or a section of a broken neck, no cheek blanches, and the overheard exclamations about the mysteries of the human body betray familiarity if not contempt. A life-size representation of the operating theatre at Bart's as it was in 1834 is also a very popular exhibit. It has wax figures of the surgeon, the nurse, and the patient in the dress of the period, with models of the instruments then used. On the other side of a partition is a replica of the operating theatre of to-day, robotique in its efficiency. An even larger exhibit of the kind figures at the stand of the King Edward's Hospital Fund, where again there are representations of the hospital methods of the pre-Listerian era, which make the spectator marvel that a patient ever survived, while the parallel exhibit of the hospital of to-day makes him wonder why a patient is ever lost. Here again the passer-by, though his eyes have been surfeited by modern furniture and his ears by gramophone records,

and even his palate by free samples of all kinds of food products, turns with an equal zest to the inspection of large-scale skiagrams, the technique of radium and light treatment, modern apparatus for the investigation of ear and nose cases, photomicrographs of blood cells, bacteria cultures, or the dreadful appearances in tropical disease. Guy's also permits a view of its operating tables and blood transfusion apparatus, and so on; but St. George's and the West London are more domestic, with, in the former, a display of garments and toys made by past and present patients and nurses, and, in the latter, a corner of the children's ward. Now that the sick-room has been virtually banished from the home, ideal or otherwise, we must feel no surprise that an exhibition of this kind should include a hospital section, and it is to be hoped that the contents of the collecting boxes which are all around testify adequately to the gratitude which the modern household ought to feel.

MEDICAL AND HEALTH FILMS

The International Institute of Educational Cinematography, which is a League of Nations organization, situated in Rome, has in preparation an *International Encyclopaedia of Educational Films* which will include a catalogue of British-made medical and public health films. The official representative of the Rome Institute in this country is the British Film Institute, and the preparation of the British catalogue of medical and allied films has been entrusted to the recent International Customs Convention, educational films will be allowed to circulate freely in the countries of those Governments which have ratified the convention, so that the existence of a comprehensive encyclopaedia of medical films will make it possible for lecturers in, and demonstrators of, medical subjects easily to obtain both British and foreign films in their special subjects. In compiling the British portion of the encyclopaedia it is necessary first to find out what medical and public health films of British origin are in existence and are actually being used for instructional purposes at the present time, and the British Film Institute therefore asks that medical practitioners and others having knowledge of such films will send particulars of them to the Institute at 4, Great Russell Street, London, W.C.1. The British Medical Association is represented on the advisory council of the Institute and on its special medical panel by Dr. G. C. Anderson, the Medical Secretary.

We regret to announce the death of Lady Berry, M.D., on April 15th. As Dr. Frances May Dickinson she was anaesthetist to the Royal Free Hospital and the Alexandra Hospital for Children. In 1891 she married Sir James Berry, F.R.C.S., afterwards president of the Royal Society of Medicine and the Medical Society of London, and together they did admirable work with the Anglo-Serbian Hospital during the war.

Dr. G. Ramon has been appointed director of the Institut Pasteur of Paris in succession to the late Dr. Emile Roux, and has also been elected a member of the Académie de Médecine.

Scotland

Edinburgh Arts and Crafts Exhibition

An exhibition in aid of the Edinburgh Royal Infirmary Extension Fund was opened in the Waverley Market, on April 7th, by Lady Rosebery. It was organized by Dr. William Robertson, late medical officer of health for Edinburgh, and a special exhibit, arranged by Dr. A. Logan Turner, illustrated the development of medical science, particularly during the last 200 years, in Edinburgh. This exhibit included portraits of celebrated medical men beginning with Hippocrates and photographs and drawings of medical institutions, to which short notes were appended indicating their respective contributions to the history of medicine. For example, a portrait of Sir J. Y. Simpson illustrated the introduction of anaesthesia, and portraits of Pasteur and Koch that of bacteriology. The King Edward's Fund model hospital, which has already been shown in London, was also exhibited. This model is constructed on a scale of $3/4$ inch to the foot, and includes faithful reproductions of hospital fittings, x-ray rooms, etc. Much interest was taken in the model, on a similar small scale, of one of the wards of the Royal Infirmary, complete with all its furnishings, this model having been constructed by the nurses and crafts men of the institution. Another series of models, also by the same craftsmen, depicted hospital practice in different ages: among these were a Greek temple of healing about 500 B.C., a Roman valetudinarium of about A.D. 200, a monastic infirmary, a sixteenth century hospital, and a ward in the early eighteenth century infirmary at Edinburgh.

Edinburgh Post-Graduate Courses

The syllabus of the post-graduate courses in medicine to be held at Edinburgh during the summer contains particulars of the instruction obtainable in July, August, and September. From July 16th to August 11th there will be a course in obstetrics, gynaecology, and child life and health, at the Royal Maternity Hospital, the gynaecological wards of the Royal Infirmary, and the Royal Hospital for Sick Children; fee £10 10s. A general practitioners' course will be held from August 13th to September 8th; it will include applied anatomy, clinical medicine, infectious diseases, clinical surgery, clinical gynaecology, child life and health, diseases of the eye, diseases of the ear, nose, and throat, and dermatology; fee £10 10s. for four weeks, or £6 6s. for two weeks. A general surgical course, to be held concurrently with the former, will include applied anatomy, general surgery, diagnosis and treatment of renal disease, abdominal surgery, gynaecological operations, orthopaedics, surgical pathology and physiology, venereal diseases, and radiology; fee £10 10s. for four weeks, or £6 6s. for two weeks. Limited courses will also be held from time to time at fees which range from £2 2s. to £5 5s., on such subjects as modern diagnostic methods, diseases of the blood, endocrinology, diseases of the nervous system, urology, x-ray physics, ultra-violet radiation, ophthalmoscopy, urological surgery, neurological surgery, diseases of the ear, nose, and throat, disorders of speech, venereal diseases, and surgical pathology. A course on clinical medicine, including radiology, has been arranged for the months of May and October, and a similar course in clinical surgery, including radiology, will be held during each academic term for a period of six weeks. Graduates may obtain the syllabus from the secretary of post-graduate courses in medicine, University New Buildings, Edinburgh.

Dental Treatment in Fife Schools

Dr. G. Pratt Yule, medical officer of health for the county of Fife, reported to a meeting of the Public Health Committee of the County Council, on April 3rd, that instances were occurring in which parents refused permission for their children to obtain school dental treatment, or in which they refused treatment recommended by the school dentists as essential. In many such cases early conservative treatment might have obviated the necessity for later extraction. The attitude of these parents was mainly the result of ignorance or of unwise sympathy towards the children. It was proposed that a propaganda campaign should be undertaken by the Dental Association in Fife during the month of June, since anything in the nature of compulsion would be harmful to the work and would reflect adversely on the county council. At the same meeting the terms of a proposed arrangement between Dunfermline Town Council and Fife County Council, concerning a new maternity home and hospital to be erected at Dunfermline, were considered.

Aberdeen University Graduation

At the spring graduation of Aberdeen University, in the Mitchell Hall of Marischal College on April 4th, the Very Rev. Principal Sir George Adam Smith presided, and conferred the degree of M.D. upon four graduates and of M.B., Ch.B. upon twenty-four graduands. The degree of LL.D. was conferred upon five honorary graduates, including Dr. Herbert Ritchie Spencer, emeritus professor of obstetric medicine in the University of London.

England and Wales

Central Midwives Board

At the April meeting of the Central Midwives Board for England and Wales Dr. J. S. Fairbairn was re-elected chairman for the ensuing year. Sir George Buchanan, M.D., and Councillor V. J. Loxley were appointed respectively as representatives on the Board by the Society of Apothecaries of London and the Association of Municipal Corporations. The Ministry of Health had forwarded a copy of a further letter from the Association of Municipal Corporations, expressing the opinion that the Board should be so constituted that representatives of local authorities should be in a majority, and that, of the representatives of local authorities, the association, as representing county boroughs and non-county boroughs, should appoint the greater number. The Board resolved: That consideration be given to the question of the reconstitution of the Board generally, and that such consideration be commenced at the next meeting. It was agreed to reply as follows to a letter from the Medical Secretary of the British Medical Association:

(1) That a midwife is only required to summon medical help if there be any illness of the patient or child, or any abnormality occurring during pregnancy, labour, or lying-in, and the summoning by her of medical help in any other instances would not come within Section 14 of the Midwives Act, 1918; (2) that the Board is of opinion that the footnote to the form of sending for medical help makes it quite clear that the midwife must not send a copy of the form to the doctor in cases in which help is sought by a relative or friend only, and the Board is not aware of any difficulties in the matter having arisen in the past; (3) that the Board has no power to decide questions regarding the payment of fees by local supervising authorities under Section 14 of the Midwives Act, 1918.

The list of examiners, as submitted for the ensuing year, was approved, and the names of Drs. A. C. H. Bell and J. D. S. Hew were added to the list of supernumerary examiners at the London centre. The list of lecturers and institutions where lectures may be delivered was approved, and also the list of institutions, homes, and midwives at which and under whom pupil midwives may be trained, subject to satisfactory arrangements on certain points being made in certain cases. The Board recorded its sincere appreciation of the service rendered by Dr. T. Vincent Dickinson as one of its members from October, 1927, to March, 1934.

New Child Welfare Centre in St. Marylebone

An appeal has now been issued by the Borough of St. Marylebone Health Society for financial assistance in building a model welfare centre and day nursery on a site offered by the Hon. Gerald Portman in the heart of the poorest quarter of the borough. The institution would comprise a school of mothercraft, treatment clinics, and a day nursery. The land presented is occupied at present by five small houses and an ex-public house, where the present child welfare work of this kind is being carried on. Since 1915, when it began, the work has far outstripped the available accommodation, and the day nursery, which has been operating since 1916 elsewhere, has been compelled to evacuate its premises, now required by the St. Marylebone Housing Association for its scheme of building much-needed flats for the working classes. The memorial fund which has been launched to commemorate the pioneer labours of the late Dr. Christine Murrell in this neighbourhood and elsewhere is to be devoted to the permanent equipment of part of the new building, with which it is proposed to associate her name. The appeal contains a short account of the efforts of the St. Marylebone Health Society since its inauguration twenty-seven years ago. Infant consultation centres and clinics have gradually grown in number, and have been combined with a school of mothercraft, a dental clinic for mothers and school children, a massage clinic, and an artificial sunlight department. The organizing secretary of the society is Miss Mostyn Bird, 9, Windsor Court, Bayswater, W.2.

Society for Relief of Widows and Orphans of Medical Men

A quarterly court of the directors of the Society for Relief of Widows and Orphans of Medical Men was held on April 11th, with Mr. V. Warren Low, president, in the chair. The deaths of four members were reported and one new member was elected. A first application for relief from the widow of a member was considered. Her late husband was elected a life member in 1921 and the widow was left practically destitute with nine children, four under 16 years of age. The court voted her a yearly grant of £60 and one of £50 a year for each child under 16; thus the yearly grant she will receive will be £260, and, in addition, she will probably receive at Christmas a present of £10 for herself and £40 for the four children. A striking example of the benefits to be derived from membership of the society. Membership is open to any registered medical practitioner who, at the time of his election, is resident within a twenty-mile radius of Charing Cross. The annual subscription ranges from two to four guineas, according to the age of the candidate. Eighty-five pounds was voted to five widows to enable them to continue their children's education, as the ordinary grants cease at the age of 16. The annual general meeting was fixed for May 8th at 5 p.m. Full particulars of the society may be obtained from the secretary, at its offices, 11, Chandos Street, Cavendish Square, W.1.

Reports of Societies

TREATMENT OF HYPEREMESIS GRAVIDARUM

At the March Meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland Dr. O'DONEL BROWNE read notes of a case of severe hyperemesis gravidarum treated by jejunostomy.

The patient was 30 years old and seven or eight weeks pregnant. On her first pregnancy she had aborted at the fourth month, and some vomiting was present. The vomiting on this, the second pregnancy, had been severe for two and a half weeks before admission to a nursing home. She presented all the signs of advanced hyperemesis, with acidosis, cracked tongue, sordes, and persistent vomiting. Constipation was present, and relieved by simple enema. Retroversion of the pregnant uterus was treated and a support inserted. Salines were given with glucose by bowel and luminal as sedative treatment. During the first forty-eight hours' treatment the condition worsened so rapidly, with development of incontinence and restlessness, that fluids were imperatively and urgently needed. Further rectal administration was impossible, the veins being collapsed and subcutaneous salines too slow to allow any of these methods.

Jejunostomy was performed under local anaesthesia. Continuous drip saline through a large rubber catheter into the duodenum was begun, and was continued for four days. Glucose 10 per cent. was added, and on the fourth day two ounces of castor oil were given by tube; and, subsequent to bowel action, whey and other light feeding, also by tube. The progress of the case was altogether satisfactory. Vomiting ceased within seventy-two hours; urine excretion and bowel action were established; the jejunostomy was closed; and the patient was sent home within two weeks. Further progress was normal except for premature stillbirth of a normally developed foetus.

Dr. Browne expressed the opinion that luminal in large doses, until restlessness was controlled, was most important. This, together with the immediate introduction of fluids with glucose, was regarded as the chief factor in the successful treatment of the condition. He did not recommend jejunostomy as a routine treatment. It was, however, seen to be of the greatest value in urgent cases such as this. Emptying the uterus appeared to be useless in the majority of cases, unless either the foetus was dead or the operation was performed at a very early stage of the disease. In less urgent cases constant drip salines with glucose intravenously were favoured. This was best done by fixation of the leg on a splint and introduction of the fluid by the saphenous vein at the ankle.

Mr. J. OWENS said that when he first saw Dr. Browne's patient he thought the outlook extremely bad. She was obviously very toxic, and there was acetone in her urine and in her breath. He opened the abdomen under local anaesthesia, through a left rectus incision. The vomit in this case was not examined for glucose. Since operating on this patient he had done two or three jejunostomies and introduced glucose and saline, and had had the vomit examined, and it had always contained glucose. It was possible to get in from five to six pints of a 5 per cent. glucose and saline solution in twenty-four hours. Dr. NINIAN FALKNER referred to a case in which he had introduced glucose intravenously, and in which the response was very satisfactory. The patient was not, however, in such a very serious condition as Dr. Browne's patient was. Most cases of severe vomiting in pregnancy that he came across he treated in this way. If patients were seen before dehydration was advanced the administration of Lugol's solution often did good.

Dr. J. CUNNINGHAM said that these cases of toxic vomiting were very troublesome, especially in hospital practice, and he thought the reason was that they did not go to hospital soon enough. He felt that in teaching sufficient stress was not laid on the importance of hyperemesis gravidarum. It was sometimes taught that induction of abortion was part of the treatment of this condition. Abortion should not be necessary, and there had never been any indication given by anybody as to when abortion should be induced. If the patient had gone as far as having the liver damaged abortion would not do any good. He himself thought that the injection of

corpus luteum and other such drugs was useless in the treatment of hyperemesis gravidarum. Patients required at least five pints of water a day, and, if possible, an effort should be made to give fluid by the bowel. If it could not be given by the bowel it could be given either intramuscularly or intravenously.

Dr. J. S. QUIN thought that most of the extreme cases of hyperemesis gravidarum were seen too late by a doctor. By the time they were seen they were usually suffering from a profound degree of dehydration with acidosis, which had to be dealt with at once. The degree of toxæmia which was present killed the foetus. In really severe cases the cause of the hyperemesis was usually not ascertained. It was presumed to be due to a toxæmia, but where the toxæmia came from was not known. It should be borne in mind that vomiting was not a natural concomitant of pregnancy.

Dr. R. M. CORBET referred to the question of getting a tube out of the rectum into the colon, and said he would not try this difficult and lengthy procedure with a patient who was in such a bad condition as Dr. Browne's. He thought it could not be done properly without inserting two fingers into the rectum. This led to pulling the patient about a good deal, in some cases more than was justifiable. He had recently removed the corpus luteum of pregnancy from a patient who was six months pregnant, and she had not vomited at all.

Dr. E. A. KEELAN referred to a case of his in which there was great distension, associated with vomiting. Jejunostomy was done and the patient made a good recovery, but in a few days she miscarried. He also referred to another case in which there was severe vomiting for four days, and intussusception. Jejunostomy was done and the patient recovered. He mentioned the necessity for teaching that vomiting in the early stages of pregnancy might be very dangerous.

The MASTER OF THE ROTUNDA said that cases of excessive vomiting were often found later in pregnancy as well as during the early stages. The pulse was, in his opinion, the real indication of the patient's condition. In one case of his recently there was albumin, and Fouchet's test was positive. She was given saline treatment. Her pulse kept going up slowly. After ten days, labour was induced at thirty-four weeks, and a live baby, weighing four pounds three ounces, was born. Immediately after the birth vomiting ceased. He felt that but for induction of labour the patient might have died.

Dr. BETHEL SOLOMONS said that this was the first case of hyperemesis treated by jejunostomy and reported from Great Britain and Ireland. Professor Moorhead, in 1919, ascribed persistent vomiting after some abdominal operations to vagus shock with motor paralysis of the stomach and over-secretion from the stomach, and suggested, when other treatments failed, that the establishment of an enterostomy opening high up in the bowel might save some patients. Sir William Wheeler had made the suggestion to him (Dr. Solomons), but a suitable case had not appeared. To Mr. Owens, who had been Sir William's assistant, great credit was due for the excellent result in the case under discussion. Mr. Victor Bonney advocated similar treatment for intestinal obstruction, which he believed to be due to spastic contraction of one segment of gut, with disturbance of gas production and gas absorption. He, Dr. Solomons, had tried various treatments for hyperemesis: he had not had gratifying results either with intravenous glucose or intensive calcium treatment. He thought it quite wrong to condemn entirely the evacuation of the uterus. All obstetricians could remember cases which might have been saved if the uterus had been emptied. Death after induction was due to the fact that the induction was carried out too late. There were many cases where the infant was dead, especially about twenty to twenty-four weeks, where minor Caesarean section, either vaginal or abdominal, was a life-saving procedure. Induction took too long and hysterotomy was attended with better results. The way to avoid deaths from hyperemesis was education, but he believed that the mothers of the patients required most education. They told these girls that vomiting was a natural part of pregnancy. Thus the specialist saw the case when it was very far advanced. Institutions seemed to vary in their

ideas as to what hyperemesis was, for the answer to a questionnaire he had circulated seemed to show that ordinary vomiting was sometimes considered as hyperemesis. He based his nomenclature on excessive vomiting, accompanied by constitutional symptoms and either the presence of albumin in the urine or a positive Fouchet test. Many serious cases would be prevented by early pre-natal attendance with instruction. Any colonic lavage or prolonged treatment would, in his opinion, have killed this patient.

NEPHRITIS

At a meeting of the Devon and Exeter Medico-Chirurgical Society on March 29th, with the president, Mr. R. WAYLAND SMITH, in the chair, Dr. F. A. ROPER gave an account of two cases which illustrated the nephrotic and azotaemic types of nephritis respectively.

The first case (of nephrosis) was that of a woman aged 41, who had had slight generalized oedema for three weeks before admission to hospital on March 16th, since when diuresis had been within normal limits and the blood pressure constant at 138 systolic and 90 diastolic. Albuminuria was considerable (1.2 per cent.); casts were present; but there were no blood cells. The urine was sterile on culture. The blood urea had been found to be 32 mg. per 100 c.cm. of blood.

The second case (of azotaemic nephritis) was that of a woman aged 48, who had been admitted to hospital on February 28th with a history of persistent vomiting for nine weeks. On arrival at hospital she was in a collapsed condition, and obviously very ill, but there was no oedema. The blood pressure was 175/104 on admission; but since the vomiting had ceased the systolic pressure had been constant at 200. Diuresis had set in after the first few days in hospital. On March 1st the blood urea was 192 mg. per 100 c.cm. of blood; on March 5th, 144 mg.; on March 16th, 67 mg.; and on March 29th, 44 mg. The urine on admission contained blood cells, albumin 0.15 per cent., and a large number of granular casts: these were now absent. The eye grounds showed evidence of arteriosclerosis, but no retinal haemorrhages were noted.

Dr. Roper said that the cases were of especial interest from the point of view of dietetic treatment. In the nephrotic type, with a blood urea within normal range, a generous nitrogenous diet had been employed from the first, whilst in the azotaemic case a diet rich in carbohydrates and low in protein had been indicated.

Dr. R. R. TRAILL mentioned the class of case in which acute nephritis with haematuria was associated with tonsillitis, and asked if, in such circumstances, Dr. Roper would recommend an albuminous diet. Dr. MARGARET JACKSON asked if bleeding had been employed in the second case, and remarked that in her experience the good effects so arrived at were not shown in the blood pressure, which tended to remain unaltered by blood-letting.

Dr. ROPER, in reply, stated that the reduction of the protein intake was of prime importance when treating cases of the azotaemic type. The nephritis referred to by Dr. Traill would probably be of a mixed type, and the blood urea figure offered the best guidance on the diet question. He certainly advocated bleeding in cases of the azotaemic type, although the collapsed state in the case just related had seemed to contraindicate this. Morphine had been decried in such conditions, but he himself had not feared to prescribe it in this and like instances.

PSYCHOLOGY OF TROPICAL RESIDENTS

At a meeting of the Medical Society of Individual Psychology on April 12th Dr. H. C. SQUIRES read a paper on "Individual Psychology and the European in the Tropics."

Dr. Squires said that he recognized the importance of exposure to the physical effects of unaccustomed temperature, light, and humidity, and to parasitic and other tropical disabilities, but emphasized that those disabilities which were sufficiently serious to result in invaliding were largely those with a cosmopolitan distribution. The lives of Europeans living under tropical conditions were worthy of consideration from the standpoint of individual psycho-

logy, not simply and solely because they were individuals, but because they were individuals in a particular setting. If certain categories of individuals were taken for comparison (and he had taken males in Government service in England and those in Government service or working as missionaries in the Tropics) certain definite facts emerged. The first was that roughly the percentage of invalidings for psychoneuroses alone, or for psychological reasons in general, to the total number invalided was three times as great for the tropical as for the home figures. Secondly, a comparison of the age groups and length of service groups revealed marked differences. The most striking of these related to invaliding for psychoneuroses during the early years of service. In England, for three years' service and under, for six years' service and under, and for ten years' service and under, the percentages were 6, 8, and 14.5 respectively. Those for the Tropics at the same periods were 41, 56, and 72. He regarded the group invalided with three years' service or less as the most important. It appeared that a transfer

to the Tropics might precipitate a state of affairs comparable to that occurring at such special epochs as the commencement of school life, adolescence, and marriage, when new responsibilities had to be undertaken in novel circumstances. Dr. Squires then discussed the motives that might lead individuals to spend a large portion of their lives in the Tropics, and the bearing of these motives on the figures already given. While realizing the importance of such factors as a family connexion and economic conditions, he said that for some individuals life in the Tropics might appear as something in the nature of an escape. Individual psychologists were especially capable of understanding such motives, which had much to do with feelings of inadequacy and inferiority. Finally, Dr. Squires gave instances to show how, under tropical conditions, such feelings might create great and sometimes insurmountable difficulties in the individual's attempt to cope with one or more of the three Adlerian life tasks—those associated with employment, society, and sex.

CORRESPONDENCE

The Milk Question

SIR,—In your issue of April 7th (p. 643), Dr. A. H. Macdonald, the chief medical officer of Dr. Barnardo's Homes, states that: "Our experience, through a succession of years, shows that tubercle is not the result of drinking raw milk." Is it possible for Dr. Macdonald to supply the evidence for this statement, and to define what is meant by "tubercle"?—I am, etc.,

Leeds, April 15th.

MOYNIHAN.

SIR,—I do not doubt the accuracy of the figures in regard to the source of tubercle bacilli in milk which have been produced by Dr. W. G. Savage (April 7th, p. 642), whose authority in respect of milk is unquestioned; but according to the People's League of Health report, upon which your leader was based (and which I confess never to have seen until this week), about 820,000 cows are infected with tuberculosis in England and Wales, and only 4,100 have udder tuberculosis. Does this latter figure account for all tuberculous infected milk, and therefore for all cases of bovine disease in the country? The true state of affairs in regard to bovine infection is not at all clear. From the same report the estimated proportion of bovine infection in non-respiratory cases in England and Wales for the ten years ending 1929 was 23 per cent., whereas, according to the report of the Central Tuberculosis Laboratory, Wales, the corresponding figure is 10 per cent. How is this difference accounted for? My own opinion is that there are not nearly as many bovine infections as is generally believed.

Two statements from the report are instructive.

"No obvious reduction in the proportion of milk infected with tubercle bacilli has occurred in the past ten years. . . . It is doubtful if pasteurization and sterilization of milk can be chiefly responsible for the rapid decline in non-pulmonary tuberculosis during the past thirty years."

No adequate explanation for this is given, but so far as bovine infections are concerned I suggest that cleaner methods of milk production are the reason, because in my opinion contaminations other than tubercle bacilli facilitate the entry of that organism. An all-round clean milk means fewer cases of tuberculosis, despite the presence of tubercle bacilli. The P.L.H. report suggests that milk from tubercle-free herds should be sold raw or pasteurized, which means that other infective organisms, whose presence is used as an argument for pasteurization, are adequately dealt with by clean methods: I am glad to find that the committee agrees with me in this. The report, however, suggests that the larger urban authorities

should be enabled to make pasteurization compulsory. The rural population does not need any such provision apparently: is it immune to milk-borne diseases? The present grading of milk is based on its degree of contamination and nothing else. Why not have clean raw milk and pasteurized milk both sold at the same price? Make the producer of contaminated milk pay the cost of the process. If you must grade it, do so according to its food value.

I maintain, as before, that pasteurization under present conditions frustrates all efforts at obtaining the clean milk supply which is essential in the first place.—I am, etc.,

Hounslow, April 16th.

W. S. FORBES.

Heredity and Mental Deficiency

SIR,—In his article in the *Journal* of March 31st (p. 584) Professor Charles McNeil rightly draws attention to the fact that the importance of the hereditary factor in the causation of mental deficiency has usually been exaggerated. I remember Dr. Robert Hutchison emphasizing this point at the meeting of the British Medical Association at Bradford in 1924.

In a recent article¹ of mine on the subject I quoted Dr. John Thomson's figures, and emphasized the need for remembering the danger to the brain of the foetus *in utero* and to the baby at birth and during the neo-natal period. We must, however, first of all be sure that the figures from which we draw our conclusions are from a study of cases which are really representative of all classes of the population, and of all types of mental deficiency. Are we quite sure that Dr. John Thomson's cases were so? I have always felt that the cases sent to a physician in consulting and hospital practice tend to be of the special types, and thus different from those seen, for instance, by a school medical officer. There is sure to be some selection as to medical interest by general practitioners and others referring cases to a physician. Dr. Manson has also drawn attention to this possible fallacy in his letter in your issue of April 7th.

In assessing the causation of mental deficiency are we to ignore the numberless instances of family trees, with the taint of feeble-mindedness running through them, and instances such as those quoted by Ireland,² where two "idiots" married and had three "idiot" children? I think that the verdict of medical practitioners who have knowledge of generations of different families, and of those who have studied the family histories of the mentally deficient, will be that there is a large element

¹ Parsons and Barling: *Diseases of Infancy and Childhood*, 1933, ii, p. 1332. Oxford University Press, London.

² *Mental Affections of Children*, Churchill, London, 1900.

of heredity in the causation of mental deficiency. The report of the Departmental Committee,² which was unanimous, should be held to be authoritative.

I hold that hereditary mental deficiency is an indefinite variation, and is to some extent due to chance, but is much more likely to occur in a psychopathic stock. Such a stock is likely to show variation either way, and thus it may well be that some of the parents of aments are highly intelligent. Furthermore, as has actually been found to be the case,³ the offspring of two mentally defective parents are not necessarily all mentally defective. They are, however, likely to be so, just as one or other of the parents of a mentally defective child is likely to be dull or feeble-minded, or to come of a psychopathic stock.—I am, etc.,

Manchester, April 10th.

C. PAGET LAPAGE.

SIR,—Whilst it will be agreed that Professor Charles McNeil is to be congratulated on the excellence of his contribution in your issue of March 31st, and on his desire to bring to wider notice the clinical study of Dr. John Thomson, on which he comments, certain observations are essential if misconceptions are to be avoided.

A reference to the universally accepted statement of the relative incidence of various grades of defect, and their classification into clinical and pathological types, in the report of the Mental Deficiency Committee, 1929, will afford convincing evidence that the cases analysed by Dr. Thomson were representative, not of mental defectives, but of the lower grades of mental defectives—a vastly different matter.

As "all of these cases were under 5 years of age at their first examination," and in face of the extremely low proportion of cases of simple primary amentia, one can hardly avoid the conclusion that the nature of the cases was such that they were diagnosable as defectives before, or at the age of, 5 years. That is to say, they consisted mostly of imbeciles and idiots, for feeble-mindedness cannot be diagnosed with reasonable certainty as a rule at the age of 5 years. That this is so will be apparent from the definition itself, without appeal to authority. The conclusions of Professor McNeil are consistent with those of the majority of investigators only if they do in fact refer to such lower-grade defectives, to the exclusion of what have recently been called sub-cultural aments.

It is also suggested that investigations which have been made in institutions for mental defectives have been criticized on the grounds that "cases regarded as hereditary tend to be concentrated there." This is not so, but rather it is the case that lower-grade defectives tend to be concentrated in institutions, and, by general consent, a relatively small proportion are hereditary.

During 1931 and 1932 I carried out an investigation into the incidence and circumstances of retarded school-children and mental defectives in a rural area of a total population of 45,000-odd inhabitants. This was presented to the University of Leeds as a thesis for a doctorate. With the permission of the senate of the University I propose, in the course of a few weeks, to submit for publication in this *Journal* a summary of that part of the thesis which relates to mental defectives and their family histories. Having said this much I do not wish to anticipate to a greater extent than to say that my findings substantiate the above observations, and lead to the conclusion that hereditary influences are evident in 75 per cent. of defectives of all grades, but much less in lower-grade defectives.—I am, etc.,

F. GRUNDY,

Assistant County Medical Officer,
East Suffolk County Council.

Southwold, April 10th.

Gonorrhoea in the Female

SIR,—Professor R. S. Statham, in his article on the treatment of gonorrhoea in the female (published on April 7th), referring to acute salpingitis as a complication of gonorrhoea, states: "This complication is known to be very rare in women who have never become pregnant, for the reason that while the internal os remains intact it is almost impervious to any organism." My experience does not bear out this statement. I am constantly coming across cases of quite young nulliparous girls, many of whom find their way to my clinic via the gynaecological department, whose first symptoms of gonorrhoea have been those of the acute salpingitis from which they were found to be suffering. I find it difficult to believe that in all these cases mechanical interference with the internal os has taken place, and that the mucous channel, along which the menses can pass in one direction and the spermatozoon in another, is impervious to the gonococcus. I have always understood this condition to be relatively common among recently married women, and have heard it referred to by at least one gynaecologist as "honeymoon appendicitis."—I am, etc.,

G. L. M. McELLIGOTT,

Director, Venereal Diseases Department,
St. Mary's Hospital, Paddington.

Definition of Menstruation

SIR,—In the *Journal* of March 24th (p. 566), "M.B.Oxon." seems to think that the conflicting views of various writers expressed in previous numbers of your estimable paper on the definition of such an apparently simple conception as that of menstruation constitute a scandal in the history of gynaecology. "As things are," he says, "many medical men must feel that the ground is slipping from under their feet." The letter seems to imply that a complete definition of menstruation which is fixed and immutable should be one of the fundamental props of gynaecology. If that prop is removed the science of gynaecology is in danger of falling to pieces like a house of cards. The writer is under the false impression that definitions in the empirical sciences such as medicine are similar to those in the abstract sciences such as mathematics. There is a world of difference. In mathematics definitions are "made," not "discovered." We construct, *at the outset*, our own definitions by a mental synthesis of certain elements, and nothing more. We do not, therefore, need the methods of induction to eliminate irrelevant conditions. These mental syntheses or conceptual definitions, which are fixed and immutable, constitute the foundation stones on which is built the superstructure of mathematical science. Conceptual definitions do not represent real things. They represent ideals or, in the jargon of philosophy, abstract universals. In the empirical sciences, on the other hand, definitions are something more than mental constructions. They claim to represent the essence or nature of real things. As these essences are given in complex reality, we have to "find" them, and not merely to construct them. They are not discovered by intuition. They are changing concepts which "grow out" of the principle of the uniformity of nature—the root principle of every branch of empirical science—by a conservation of the "essentials" and the elimination of the accidentals. Mathematical definitions, then, constitute the solid foundation stones of a magnificent piece of architecture which laughs at nature. Real or empirical definitions, on the other hand, have a growth and development like that of a living organism in which the accidental variations are rubbed off by the process of trial and error. As we shall soon see, the differences of opinion on the definition of menstruation which have so

upset the faith of "M.B.Oxon." should not be regarded as flat contradictions. They represent, rather, different stages in the development of that definition.

Until comparatively recently menstruation was defined as a periodic shedding of blood from the uterus occurring at the time of ovulation. In the light of further experience it was discovered that menstruation, instead of synchronizing with ovulation, did not take place until approximately fourteen days after that event. I need hardly say that it took some considerable time before the new definition was accepted. Further investigation appeared to show that decidual necrosis was an essential feature of the menstrual process. Within the last few years anovular menstruation, accompanied by endometrial change, has been observed in monkeys by Corner and others during a certain season of the year. According to Novak and other accredited observers, the persistence of the interval type of endometrium throughout the entire menstrual cycle of the human female at all seasons of the year is not an uncommon occurrence. This can be interpreted only to mean that anovular menstruation occurs in women as well as in monkeys. Wilfred Shaw does not deny the possibility, but he regards anovular menstruation in women as pathological, not physiological. The distinction between what is pathological and what is physiological is based so frequently upon pragmatic or human, rather than upon logical, considerations that the pathological category is a convenient *pot pourri* which receives everything that fails to agree with preconceived notions. "What," says Hartman, "could we not learn of normal physiology by salvage from this heap!" The "premenstrual endometrium" and "intermenstrual bleeding" have already been rescued from the category of the pathologic. There are equally good grounds for elevating anovular menstruation from the rubric "pathologic" to the "physiologic." In order to keep within the facts it would appear that ovulation is not an essential part of the mechanism of menstruation.

The periodicity of menstruation, which is, after all, its most fundamental and impressive feature, has been traditionally regarded as, *sui generis*, entirely unrelated to the oestrous and reproductive cycles of the lower animals. Studies in comparative physiology have disturbed the traditional view. In a paper which I contributed to the *British Journal of Obstetrics and Gynaecology of the British Empire* (1931, xxxviii, No. 4), I indicated many arguments, both histological and biochemical, in support of the view that in ovulatory menstruation the oestrous and reproductive cycles during the second half of the menstrual cycle are telescoped into each other, so to speak. In anovular menstruation there is only one cycle—the oestrous cycle. If this view is accepted, then we shall have to reconstruct our definition of menstruation in order to harmonize it with the findings of comparative physiology and biochemistry. In the paper of mine to which I have already referred I have defined menstruation to be a *periodic shedding of blood from the uterus during the child-bearing period which, accompanied by ovulation, represents pro-oestral and pseudo-pregnant degeneration telescoped into each other: unaccompanied by ovulation it represents pro-oestral degeneration alone.*

We must carefully distinguish between the nature or meaning of menstruation as defined and its causality. A solution of the former is logically prior to that of the latter. It is obvious that we must know what a thing is before we can account for its causality. The unfolding of the nature of menstruation is not an instantaneous affair. It is a long-drawn-out affair, like the growth of a living organism, as I have already said. We should expect, therefore, a corresponding development of the causal concept, and that is really what we find. How-

ever, we are concerned at present with the definition of menstruation, not its genesis or causality.

I agree with "M.B.Oxon." that the various writers expressed their conflicting views upon the definition of menstruation in language that was indecorous and intemperate. Dr. Wilfred Shaw was hardly fair to the reputation of such a world-renowned gynaecologist as Novak. A dignified protest by the latter called forth, I am glad to say, a handsome apology from Wilfred Shaw. Professor Blair-Bell's letter to the *Journal* did not help to mend matters. In his defence of Novak and the American school from the unwarranted attack of Wilfred Shaw he tried to belittle the reputation of the latter. Shaw's reputation in histological research, which has thrown considerable light on menstruation and menstrual disorders, is assured. I do not suppose that the deliberate omission by Blair-Bell of Shaw's name from the new edition of the *Principles of Gynaecology* will dim the lustre of that reputation.—I am, etc.,

D. J. CANNON, M.B., B.Ch., M.A.O.

Infirmary House, Kildare.

Leucocyte Counts

SIR,—In a leading article in the *Journal* of March 31st, on the normal leucocyte count, you state that "the numbers of leucocytes in the peripheral blood are subject to wide and rapid fluctuations," and, further, that a series of counts performed regularly on a single individual at the same time of day betrayed "only a capricious irregularity."

I have for some years been carrying out detailed blood counts on the same lines in both "normal" and tuberculous individuals, but I have always obtained the sample of blood from a vein in the antecubital fossa. Working with venous blood, I have carried out counts at intervals of from half an hour to twenty-four hours in the same individual, and again at the same hour each day for two or three weeks. I have found the daily fluctuation in the total leucocyte count to be seldom more than 1,000 cells per c.mm. in the absence of clinical change in the subject, or of the injection of vaccines, etc. I have satisfied myself that, apart from minor variations, the percentages of cells in the differential count remain reasonably constant from day to day. I feel sure that the unsatisfactory results which have been obtained by using specimens of blood extruded from the capillaries and tissues are dependent, as your leading article suggests, on local conditions.—I am, etc.,

Colindale Hospital, London, N.W.9,
April 10th.

L. E. HOUGHTON.

Liver Therapy in the Tropics

SIR,—With reference to the article in the *Journal* of March 31st (p. 578) on "Pernicious Anaemia in an Asiatic," I was very much interested in Dr. Spaar's account of his treatment of this case.

It is satisfactory to note that, although the progress of the case was slower than one usually experiences in the treatment of cases of pernicious anaemia with liver therapy, the result was eventually satisfactory. I think that the explanation of the slow response is more or less apparent. On studying the blood counts on various days in relation to treatment it is at once evident that treatment with hepatex P.A.F. was instituted prior to the removal of six septic stumps. From my own personal experience of rather similar cases in this country I am satisfied that the presence of septic stumps, or in fact any septic focus, is quite sufficient to diminish seriously the effect of liver therapy, and in all probability, had the septic stumps been removed in this case prior to the institution of liver therapy, the response would have

been very much more satisfactory and progress more rapid. I think that Dr. Spaar is probably mistaken in assuming that preparations of liver extract are prone to deteriorate in the Tropics, since it is not in accordance with many reports I have received from other tropical sources, in which it has been found that liver therapy has proved quite satisfactory, not only in the treatment of pernicious anaemia, but also in sprue.—I am, etc.,

Runcorn, Cheshire, April 4th.

H. A. MITCHELL, M.D.

The Human Factor in Road Accidents

SIR,—The Road Traffic Bill, which has just passed its second reading in the House of Commons, should arouse particular interest in the medical profession for two important reasons. The first, and the more weighty, lies in the circumstance that it is the medical profession which can contribute more successfully than any other agency to the prevention of accidents. The second and more trivial reason is the grievance which the profession undoubtedly feels in that it carries the burden of first-aid in injuries, often without any corresponding remuneration.

An admirable little pamphlet, a copy of which I enclose, has been published within the last three months by the National Institute of Industrial Psychology, a body whose work and very existence is too much ignored both by the public and by the profession.* I have chafed Lord Macmillan, who is President of the Institute and also Chairman of the University of London Court, on the relative failure of the Institute in making its work more widely known. I hope that this letter may attract the attention of some of my colleagues to the importance of the new methods, devised largely by the Institute, for testing motor drivers.

I made an effort, but without success, during the debate on the second reading to induce the Minister of Transport to give some consideration to the human factor in the production of accidents, a factor which the Bill almost completely ignores. The experience of the medical profession, acquired after long observation of factory accidents, has surely convinced everyone familiar with the subject of the predominant importance of the human factor in the production of accidents. In his report for 1932 the Chief Inspector of Factories makes the significant observation that however perfectly machinery may be guarded not much more than a further 10 per cent. reduction in the appalling present factory accident rate could thus be effected, but by consideration of the human as against the mechanical factor a much more hopeful outlook could be entertained. Too little study has been given to this factor, and the new psychological and physical tests are opening up a very wide prospect of success in the prevention of accidents, both in factories and on the road.

In a very interesting paper by Dr. Charles S. Myers, F.R.S., Principal of the National Institute of Industrial Psychology (*The Review*, March 9th, 1934), he says:

Factory and traffic accidents are believed by the psychologist to be due to precisely the same causes as are found to determine the breakages of cups and saucers in a restaurant. These accidents are not equally spread among all who might be subject to them. They are more frequent among novices who have not acquired sufficient skill; they are more frequent among the youngest and oldest; they are also more frequent among certain individuals ("accident-prone" persons, as we shall later call them), however experienced or of whatever age they may be. Further, they are more fre-

quent during conditions of over-pressure, irritation, and worry or other causes of excitement. The frequency curve of the breakages of china obtained for different hours of the day, at the start of the investigation just mentioned, showed an enormous rise between the hours of 4 and 6 p.m., when fatigue from the day's work might be supposed to reduce the dexterity and caution of the waitresses. But fatigue alone is probably not a prime cause of increased breakages, nor, indeed, of any other accidents, whether in the factory or outside it. It is more especially when, in the presence of fatigue, undue effort is made to maintain speed that accident frequency is increased; and in restaurant work this condition must be most acute at the last of the "rush" periods of the day. Other causes of accidents have also been ascertained. Factory accidents, for example, tend to occur with more frequency on Mondays and towards the week-ends; also under conditions of uncomfortable temperatures, both hot and cold, of defective lighting, and of bad ventilation.

The breakage of human bodies is surely of more importance than the breakage of cups and saucers, and is even more deserving of close scientific attention. Unfortunately, the opportunity for accurate observation and study of traffic accidents has hitherto been scanty, but there is some material for gauging the practical utility of selective tests in cases where they have been applied.

Thus Myers mentions a batch of American drivers divided into two groups, one having a high, the other a low, accident rate. Forty-nine per cent. of the high accident group (but only 9 per cent. of the low accident group) were suffering from bodily infirmities, easily determined by medical examination. Forty per cent. of the high accident group (but only 12 per cent. of the low accident group) failed to pass a certain single laboratory test to provide help in selecting reliable drivers. The tests employed by the Institute are intended to ascertain the accuracy, speed, and uniformity of speed, of responses to various signals; the ability to distribute attention effectively and to resist distraction; visual acuity and binocular balance; the ability to estimate rapidly and accurately the size and distance of other vehicles, etc. Myers gives a very remarkable example of the practical utility of selection tests when properly devised and applied. Thus in Paris, whereas the frequency of accidents caused by taxis, private cars, and lorries (in which no tests were applied) increased between the years 1923 and 1932 by 145 per cent., the accident frequency caused by the omnibuses and trams of the General Transport Company of Paris, since their use of selection tests during the same period, decreased by 30 per cent., and incidentally the company using these methods found that it effected an annual saving of over 1,500,000 francs. The saving in the reduction of the wear and tear of the vehicles driven by the better selected man would be difficult to estimate, but must be a very considerable additional asset. It is further to be noted that in many of the cases the fault ascertained by these methods can be corrected in the individual. It was found, for example, that a reduction of 42.7 per cent. in accident frequency among the accident-prone group was obtained after six months' instruction and treatment.

It is, of course, essential that these tests should be carried out by experts, and it may be objected that the cost would be prohibitive. In this connexion a pertinent observation is made by the secretary of the Pedestrians' Association. He points out that the Royal National Lifeboat Institution maintains a lifeboat service at an annual cost of nearly £300,000, mostly obtained from voluntary sources. The average number of lives thus saved from drowning in a year is from 300 to 400. The accidents due to motor cars on our roads for the year 1933 were responsible for 7,125 killed and 216,401 injured. I believe that public opinion is sufficiently aroused by these figures for its consent to be readily obtained to an enlarged expenditure designed to reduce the toll of the roads, and the medical profession is clearly marked out as the agent, both to convince the public on this matter and to supply the most effective remedy against road

* Issued by the Institute, Aldwych House, W.C., price 3d.

accidents. If pressure were exercised by the medical profession I believe that a clause insisting upon the use of these new scientific methods might still be inserted in the Bill before it becomes an Act, and it is with the object of arousing the profession to apply such pressure that I write this letter.—I am, etc.;

E. GRAHAM-LITTLE,
Joint Chairman with Viscount Cecil of the
Road Accidents Parliamentary Group.
House of Commons, April 11th.

Hypochondriasis

SIR,—Dr. T. A. Ross (April 7th, p. 643) need not be alarmed. Having survived encounters with several naval commanders, I do not intend to reach your obituary column through an infuriated army colonel (retired). So if I have such a patient I shall certainly not tell him that he has failed in his career; but I shall hope that he will be drawn to tell me that his ambitions have been frustrated, and if he does so, I think it will help him. He may even recollect that, as a small boy, his not too sympathetic parents paid him special attention when he had a bilious attack, and possibly see the persistence of his life-style in the similar situation as regards his wife and his abdominal discomfort. I agree that it is probably very difficult to help retired colonels by "radical cure"; but does this mean, as both Dr. Hutchison and Dr. Ross insist, that we must not try? Dr. Ross believes in "giving the patient the feeling that he is being taken care of" (what would the colonel's reactions be if he overheard that remark?); but, surely, what the patient needs is sympathetic understanding.

I agree with Dr. Ross that "if there were no compensation for accidents there would be no traumatic neuroses," but there are many forms of compensation: the little lady I was called to see last night, howling tremendously over a very slight graze, had found hers in the fuss she was getting from her grandfather. Is it unreasonable to suggest that she, too, finds parental understanding somewhat lacking?

As for the vicarious hypochondriacs, does not a feeling of guilt *ipso facto* connote a feeling of inferiority to those who are not guilty? Whatever the unconscious factor, however, this class certainly presents a very difficult problem, which every one of us comes up against—notably in Dr. Hutchison's apt example of the over-anxious parent. I venture to suggest that the person who is in the best position to tackle this problem—if he cares to try—is the family doctor, not only because it is easier to get these patients to his consulting room than to Harley Street or to hospital, but also because he is likely to see them in an earlier stage than Dr. Hutchison or Dr. Ross. Most mothers who are anxious about their children will respond to a tactful inquiry about their own health; and it is obvious that the mother who has only one child both lacks the confidence that comes from rearing six and is extremely likely to be suffering from some unsatisfactory and uncertain method of birth control. Let us do what we can by re-education on the conscious level; but is that sufficient?—I am, etc.,

Wandsworth, April 9th.

F. GRAY.

The Medical Witness

SIR,—I observe with interest not unmixed with sadness that your medico-legal authority, in warning the doctor to avoid technical phraseology when giving evidence in court, is unable to refrain from repeating that time-honoured monstrosity of pathological hyperbole which the learned judge translates as "a black eye."

Whenever a book on forensic medicine or an article on the subject of medical evidence is published, one looks with confidence for this venerable example of our traditional inability to avoid unnecessarily long technical terms. I confess I have always regarded the doctor who was originally responsible as a lineal descendant of Mrs. Harris: the choice perfection of the composition smells too much of the lamp. It is, however, possible that it really issued from the lips of a colleague whose desire for accuracy and whose fluency were indeed to be envied, even if his lamentable lack of a sense of proportion was to be deplored; and in all sincerity I asked in your hospitable columns nine years ago if one of your readers as inquisitive and as sceptical as I, but more enterprising, could supply chapter and verse. Now, nine years later, I would again humbly suggest to learned writers on medico-legal topics that it really is time that we were entitled to receive, during the course of instruction when we are to be flagellated for our inability to express ourselves in plain non-technical (yet unpatronizing) language, another example of what ought not to be said: one which is quite as convincing and, if I may say so, much more probable.—I am, etc.,

London, W.1, April 14th.

ADOLPHE ABRAHAM.

The Election to the Council of the Royal College of Surgeons

SIR,—The excellent effect which followed the letter from Mr. Ivor Back which you published in April, 1928, seems to have lasted for about five years; for, with the exception of the curious incident to which he refers in his letter appearing in your issue of April 14th (p. 689), peace has reigned since. But now the canvassers show signs of stirring again. If his present campaign, as I hope it will, proves equally effective for another five years, may I suggest that you will allow Mr. Back the courtesy of your columns to issue, at the proper intervals, a quinquennial appeal to Fellows of the College to abstain from the tiresome and undignified practices which he describes so well. He would earn the gratitude of many besides myself.—I am, etc.,

London, W.1, April 13th.

LIONEL COLLEDGE.

SIR,—Mr. Ivor Back's letter has much impressed me. That a Fellow of the College should be obliged, in the interest of medical ethics, to state his case on the unholy method of wire-pulling in the election of the Council is indeed distressing to learn and sad to contemplate. It was as if one of the immortals had made his way into the very presence of the gods with a genuine grievance to be laid at the feet of Zeus, who, as was his wont, sits on his throne saying nothing, but enigmatically "nodding assent." We members of the College are, of course, mere mortals, but our existence, we are told, is sometimes felt. Our grievance has been issued annually for over forty years. Is it not appalling that so important a reform as representation of members on the Council of the College should not be acceded? But the gods on Olympus, who are omnipotent and superior in every respect to the "man-in-the-street" member, can exercise their autocracy. This is an age of dictators.

If examination is considered the only test of special knowledge in any given subject, the exacting requirements in anatomy, physiology, and surgery for the Fellowship speak for themselves. But, Sir, I should be interested to learn whether members of the Council are required to pass any examination in the history of medicine, ethics, or the

art of statesmanship; if not, a knowledge of surgery alone can hardly help them in the enlightened ruling of those whom they are supposed to direct. The member is surely the man who, by his special experience, knows the requirements of the general practitioner better than your surgical specialist or consultant. An amalgamation of the two would undoubtedly strengthen the cause of each, and could not but add to progress in surgical practice throughout the British Empire. The British Medical Association has given proof that among general practitioners there are many who possess the combined qualities of organization, judgement, and foresight.—I am, etc.,

London, N.8, April 17th.

T. WILSON PARRY.

Medicine and Economics

SIR,—No medical man will dispute the proposition that there is an intimate connexion between economics and the physical and mental well-being of the people, and therefore between economics and the practice of medicine. For those of us whose lot is cast in the industrial districts especially, the results of the depression of the last few years have been only too apparent. The economic circumstances of our patients merely make a mockery of any scientific enthusiasm we manage to retain, and fill us with a sense of futility and frustration. When the whole scheme of living is wrong, and we know it, economic conditions leave us no resource but the hypocritical offering of a bottle of medicine, or a box of powders, with the addition, perhaps, of some advice which we know cannot possibly be carried out. I submit, Sir, that if the medical profession is to justify the position of trust which it holds in the estimation of the people, it should welcome any movement which promises a solution of the present economic chaos and a raising of the standard of living of the mass of the people.

It may be argued that economic problems are outside the scope of a medical journal, and that in any case they should be left to the experts in that subject. In reply, I would suggest, first, that the concentration of the medical man on his own professional responsibilities scarcely absolves him from the wider responsibilities of citizenship, and, secondly, that the "experts" are not making much of a job of it. So little progress are they making, in fact, that thinking people all over the country have been driven to examine the facts for themselves, and there is a steadily increasing volume of opinion that the root cause of our difficulties is to be found in the operation of our banking and financial system.

Up till recently there has seemed to be a conspiracy of silence with regard to this question on the part of the Press, but on April 4th the London Times earned the gratitude of the country by opening its columns to a discussion on this subject. The discussion was initiated, as perhaps you are aware, by the publication of a letter signed by several well-known and influential gentlemen, expressing their opinion that the financial system stands in need of reform, and pleading for a scientific inquiry into the whole question.

My object in writing is to suggest that the British Medical Association should throw its weight into the scale, and should bring to the support of this demand the assistance of its prestige and authority. A scientific body cannot possibly object to a scientific inquiry, the demand for which would acquit you of any *a priori* opinions. I submit, finally, that the course suggested would raise the Association immensely in the estimation of all who sincerely desire to find a way out of the present deadlock.—I am, etc.,

A. C. DOUGLAS.

Dunfermline, April 8th.

Lymphadenoma

SIR,—May I call attention to a slight inaccuracy in your otherwise admirable report of my contribution to the discussion on lymphadenoma, at the Royal Society of Medicine on March 27th? Referring to methods of regional irradiation I said that Finzi had applied the term "radiation baths" to this type of treatment, but in your report the term "radiation bars" was used in error. Dr. Finzi was unable to be present at the discussion, but he writes to say:

"I think you take much too gloomy a view about these cases. I have now quite a number of cases over five, ten, and even fifteen years where extensive local treatment, combined with treatment of the adjacent gland areas, has resulted in a complete disappearance of the growth without recurrence. Most of them are cervical, but one was a case of a man with enormous masses in his groins."

I am glad to take the opportunity of correcting any excessively pessimistic impression I may have given in my paper.—I am, etc.,

London, W.1, April 14th.

WALTER M. LEVITT.

Obituary

JAMES ANDERSON, M.D.

Seaton Delaval

By the death on April 6th of Dr. James Anderson of Seaton Delaval a popular and highly esteemed personality has been removed from East Northumberland. Born in 1866 he was educated in the Universities of Edinburgh and Durham. He graduated M.A.Ed. in 1887 and M.B., C.M. in 1891, following these seven years later with the B.Hy.Durh. He proceeded M.D. with commendation in 1922. He had been in practice in the extensive colliery districts of Seaton Delaval and Cramlington for about forty years, and had been medical officer of health to the Cramlington urban district council for some thirty years. He took a very active interest in the work of the St. John Ambulance Brigade, being assistant commissioner for the northern section, and a Commander of the Order. He was a Fellow of the Society of Medical Officers of Health. Dr. Anderson rendered conspicuous service to public education, and had been chairman of the Seaton Delaval Education Committee of the county council. A month ago he was re-elected to the Northumberland County Council, on which he had previously served for six years. He was also a justice of the peace, and regularly attended the courts of Blyth and Whitley Bay. He was a member of the Grand Lodge of Freemasons, and a founder member of the Astley Lodge, Seaton Delaval. James Anderson joined the British Medical Association in 1892, and was chairman of the Blyth Division from 1923 to 1927. He was a member of the Representative Body at the Swansea Annual Meeting of the Association in 1903, at Exeter in 1907, at Newcastle-upon-Tyne in 1921, at Portsmouth in 1923, and at Edinburgh in 1927. He was a member of the Local Medical and Pael Committee of Northumberland from its inauguration, and chairman during the last three years.

Dr. WILBUR C. LOWRY (honorary secretary of the Blyth Division) writes: Many of us younger members of the Blyth Division and of the Panel Committee will long remember how with a thoughtful mien or a cheery smile and a characteristic "No" Dr. James Anderson's forceful personality waved aside objections and opposition alike. No resentment was ever felt, because we knew he had a "flair" for getting things done. Dr. Anderson possessed in large measure the art of the practice of medicine. He also kept in close touch with the advance of scientific

medicine. He attended the scientific meetings regularly, and took part in the general discussion. A survey of the organizations and individuals who paid tribute to his memory impresses on one the multitude of his interests and the influence he exercised even beyond the district in which he lived and practised. It also marks the standard of his ability to deal with men and affairs. He will be greatly missed by his fellow practitioners in medico-political and scientific matters. He will be missed by the St. John Ambulance Association, and not least by the classes who regularly asked if he was available to examine them.

ANDREW MCFARLANE, M.D., M.R.C.P., D.P.H.

Medical Officer, Scottish Board of Health, and late Deputy Medical Officer, Darlington

We record with much regret the death, in Edinburgh on April 2nd, of Dr. Andrew McFarlane, after a prolonged illness. Born at Leadhills in 1898, Andrew McFarlane was educated at Biggar Grammar School and the University of Edinburgh. He graduated M.B., Ch.B. with honours in 1922, and proceeded M.D. in the following year. He early revealed a remarkable facility for absorbing knowledge and passing examinations, and he followed his earlier successes with the obtaining of the diploma M.R.C.P.Ed. in 1926 and the D.P.H. in 1927. His first appointments were in Edinburgh, where he was house-physician at the Royal Infirmary, resident medical officer to the Ministry of Pensions Hospital, clinical tutor at the Royal Infirmary, and medical officer at the tuberculosis hospital, and he held clinical assistantships at the tuberculosis dispensary and the venereal department of the Royal Infirmary.

With such a wide grounding McFarlane started on what seemed certain to be a most distinguished career in public health. For two years he was assistant county medical officer of health in Surrey, and in 1929 was appointed to Darlington from a long list of applicants. In that town he was deputy medical officer of health, medical officer for venereal diseases, and assistant school medical officer. In November, 1933, he was appointed medical officer to the Scottish Board of Health, but increasingly grave illness prevented him from taking up the duties. Two operations proved unavailing, and an exceptionally promising career was untimely ended. To his brilliance of attainments and outstanding abilities he added a charm of manner which rendered him generally popular, as well as greatly respected. A keen golfer, he carried off several honours at the Dimsdale Spa Golf Club. He leaves a widow, a son, and a daughter, with whom deep sympathy is felt. He became a member of the British Medical Association soon after graduation.

NORMAN LAVERS, M.D.

We regret to record the death, on March 26th, of Dr. Norman Lavers of Bath, after a professional life devoted to the study and treatment of mental diseases. Born in Tasmania in 1872, he received his medical education at Guy's Hospital, where he had gained an entrance scholarship in arts. He obtained the diplomas M.R.C.S., L.R.C.P. in 1896, and three years later the M.D. Brux. degree. After holding the post of assistant medical officer at Cumberwell House, London, he brought into being the city and borough mental hospital at Canterbury, and became its first medical superintendent. He later went to Bath as medical superintendent of Ballbrook House, remaining there for twenty-one years, until his retirement from practice. A keen member of the Royal Medico-Psychological Association, he served for some time on its council. He joined the British Medical Association in 1908, and was a member of the Representative Body

from 1915 to 1920. He held office as chairman of the Bath Division in 1922-3, and when the Association held its Annual Meeting at Bath in 1925 he was a vice-president of the Section of Neurology and Psychological Medicine. He was also president of the Bath Clinical Society. Dr. Lavers was a Freemason, and a member of the Bath Lodge of Honour. During the war he held a commission in the R.A.M.C., worked at the Bath War Hospital, and also at Aintree and St. Annes in connexion with the treatment of shell-shock. He had moved not long ago from his house at Clifton Down to the countryside at Box.

A colleague, F. H. E., writes:

Norman Lavers was an all-round sportsman. He played regularly for Guy's at soccer, and, whilst a student, occasionally for the county of Surrey at cricket. I remember his sometimes uncanny skill with a billiard cue, and later in life he showed the same aptitude with a rod. It is often difficult to recall the particular attribute that differentiates a man from his fellows, but in Norman Lavers it may be that it was his thoroughness: how he did what he set himself out to do, in work or in play, will stand out in the memory of his many friends, and to this may be added a natural placidity of temperament, the gift of silence when it was best, the wise word in due season, the ear of a patient listener—rare attributes, and he had them all. He leaves a widow and three sons.

THE LATE DR. STANLEY MELVILLE

Dr. H. B. PADWICK (Bedford) writes:

To the appreciative obituary notice of the late president of the British Institute of Radiology, Dr. Stanley Melville, and of his attainments in the radiological world there must be many who knew him as a man who felt, on reading it, that they would like to add something on the personal side. Perhaps it may be permitted, to one whom he sought unasked to help on more than one occasion, to stress a particular side of his character. If Melville had a hobby it was helping other people. In fact he spent his life in assisting his fellow men, both individually and as members of a corporate body. But for him the Institute of Radiology might not still be in existence, and even now, when it is firmly established, "the Institute" without Melville is melancholy to contemplate. There are quite a number of radiologists now practising whom he has "made" professionally, and who would be the first to admit it. I can think of two particularly prominent exponents of that branch of medicine who continually do so. Yet he was the most unobtrusive of benefactors, and anything like patronage was entirely foreign to him. In his room, for instance, at the Brompton Hospital, which was apt to be thronged with visitors anxious to hear his words of wisdom on chest films, he, who saw many thousands of such films a year, would turn, when a difficult one was put up, to an obscure provincial radiologist and humbly ask his opinion on it, waiting with an air of unaffected deference for his halting reply. There was something about his courtly manner and his frank straightforward approach which—as a manufacturer said to me last week—made all with whom he came in contact feel that here was a man one could trust. A very white man and a big man in every sense of the word—one with whom one could be frivolous yet whom it was instinctive to address as "Sir." However busy he might be one was always assured of a welcome. He had always time to give an opinion on a film, and such was his enthusiasm for his work that he always demanded more. The world is indeed the poorer for the passing of a very great gentleman.

Dr. ROBERT WILLIAM MAYSTON of Erith, who died on April 3rd at the age of 58, was the elder son of the late Engineer Rear-Admiral R. Mayston, C.B., and was educated at Portsmouth Grammar School and Guy's Hospital. In 1897 he obtained the diplomas M.R.C.S.,

L.R.C.P., and graduated M.B.Lond., with honours in forensic medicine. He proceeded M.D. in 1899. After holding the appointments of house-physician to Guy's and house-surgeon at the Seamen's Hospital, Greenwich, he was appointed medical officer to the Erith Armament Works in 1900. Three years later he entered into partnership with the late Dr. Murison of Erith. He held the rank of captain R.A.M.C.(T.), and was lecturer to the Erith Branch of the St. John Ambulance Brigade and surgeon to the Erith Cottage Hospital. He joined the British Medical Association in 1911, and held office as chairman of the Dartford Division in 1927-8. His health had been impaired since an attack of pneumonia seven years ago, and for the last two years he had been almost entirely confined to bed.

We regret to record the death, on April 7th, of Dr. PETER WILLIAM MACDONALD of Weymouth, who had been a member of the British Medical Association for fifty-three years. Dr. Macdonald received his medical education at Aberdeen, where he graduated M.B., C.M. in 1879, and proceeded M.D. in 1886. His professional life was almost entirely devoted to the study and treatment of mental diseases, and he was early appointed to the post of assistant medical officer to the Cheshire County Asylum at Parkside. For many years subsequently he was well known and highly esteemed as the medical superintendent of the Dorset County Asylum at Herrison, and after his retirement was honorary visiting physician to that institution. A keen supporter of the Royal Medico-Psychological Association, he was honorary secretary of the south-west division from 1894 to 1905, and occupied the presidential chair from 1907 to 1908. He was an early pioneer in the work of localizing mental function, and contributed articles on this subject to the *Journal of Mental Science*. He served on the Neurological Pensions Board for the Dorset and Bournemouth area. Dr. Macdonald was elected a member of the British Medical Association in 1881, and did all in his power to assist its work. He was chairman of the West Dorset Division in 1922-3, and a past president of the Dorset and West Hants Branch, and had also filled the presidential chair of the Bournemouth Medical Society. After his retirement he removed to a house on the outskirts of Weymouth.

Dr. CHARLES MICHAEL COOKE died on April 13th, at the age of 70 years, at his home in Northam, Devon. He was trained at St. Mary's Hospital, London. After qualifying as M.R.C.S., L.R.C.P. he practised for many years at Barnstaple, where he was in partnership with Dr. J. W. Cooke, his brother. For twenty years he was parish medical officer for Barnstaple. Whilst at the height of his career, and in the prime of life, he became totally blind. Undeceived by this handicap, he trained as a blind masseur, and was duly certified by the National Hospital and University College of the School of Massage. For twenty years he resided at Northam, where he established an extensive practice as a masseur in Bideford and district. He was appointed masseur to the Bideford and District Hospital. During the last two years he relinquished active work on account of a breakdown in his general health. On leaving Barnstaple, owing to blindness, the local medical men issued an appeal on his behalf to the medical profession at large. As a result of the generous response, a fund was raised which enabled Dr. Cooke to live in comfort for the rest of his days. Reference should also be made to the generous help afforded the late Dr. Cooke by the National Institute for the Blind.

We regret to announce that Dr. MARTHA KEITH, assistant medical officer of health and assistant school medical officer for the city of Norwich, died on April 8th. Dr. Keith studied medicine at the University of Edinburgh, and immediately after graduating M.B., Ch.B.Ed., in 1926, she became a member of the British Medical Association. In 1930 she obtained the Edinburgh D.P.H.

Universities and Colleges

UNIVERSITY OF LONDON

The ceremony of presentation for degrees will take place at the Royal Albert Hall on Thursday, May 10th, at 2.30 p.m. The annual service for members of the University will be held at Westminster Abbey at 5.30 p.m., when the Dean of Exeter (the Very Rev. W. R. Matthews, D.D.) will preach. The graduation dinner will take place in the evening at the Leathersellers' Hall, when the Chancellor will preside.

The University College Committee has re-elected Sir John Rose Bradford, Bt., M.D., F.R.S., as chairman, and Lord Meston as vice-chairman, for the year 1934-5.

Dr. G. H. Eagles has been recognized as a teacher of bacteriology at the Lister Institute of Preventive Medicine.

The regulations of the University Studentship in Physiology (Scholarships Pamphlet, p. 25) have been amended by the substitution for paragraphs 5 and 6 of the following:

5. The names of all candidates will be submitted not later than May 1st to the Board of Studies in Physiology, who will nominate appropriate assessors.

6. Applications must be received by the Principal on or before April 20th, 1935.

Dr. A. M. H. Gray has been appointed representative at the celebration to be held in honour of the hundredth anniversary of the foundation of the Medical School of the University of Liverpool on May 11th and 12th, and Professor W. W. Jameson representative at the forty-fifth congress and exhibition of the Royal Sanitary Institute at Bristol from July 9th to 14th.

Lectures

A course of three lectures on "Experimental Vertebrate Embryology" will be given by Professor W. Vogt, professor of anatomy in the University of Zürich, at University College on May 22nd, 24th, and 25th, at 5.15 p.m. At the first lecture Professor J. P. Hill, F.R.S., will be in the chair.

A course of three lectures on "Some Problems of Perception in Modern Psychology" will be given by Professor David Katz, formerly professor of psychology in the University of Rostock, at Bedford College on May 22nd, 23rd, and 24th, at 5.15 p.m. At the first lecture Mr. C. A. Mace, Reader in Psychology in the University, will be in the chair.

UNIVERSITY COLLEGE

A course of eight public lectures on "The History of Physiology" will be given by Professor Charles Singer, M.D., and Dr. K. J. Franklin in the Department of Physiology and Biochemistry on April 30th, May 1st, 2nd, 7th, 8th, 14th, 15th, and 22nd, at 5 p.m. The lectures are open to the public without fee or ticket.

BEIT MEMORIAL FELLOWSHIPS

An election of junior Fellows will take place in July. The annual value of a junior Fellowship is £400, and the usual tenure for three years. Forms of application and all information may be obtained by letter only, addressed to the honorary secretary, Beit Memorial Fellowships for Medical Research, University College Hospital Medical School, University Street, W.C.1. Applications should be received by May 18th, though later entries will be accepted up to June 1st.

LONDON HOSPITAL MEDICAL COLLEGE

An open entrance scholarship (value £100), offered by the London Hospital Medical College, has been awarded to A. F. Smith of Lincoln College, Oxford.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A quarterly Council meeting was held on April 12th, when the President, Sir Holburt Waring, was in the chair.

Diplomas of Membership were granted to Thomas Stewart Heslop and Maxime Shun-Shin. Diplomas in Tropical Medicine and Hygiene were granted jointly with the Royal College of Physicians to the following twenty candidates:

A. C. Banerjee, F. P. Bhavnagri, S. A. B. Black, I. E. Dickre, V. L. Ferguson, Emily C. Greenfield, R. D. Harding, L. C. Mayne, K. S. Menon, T. H. L. Montgomery, M. G. Pradhan, H. A. F. Sallam, M. F. Seif, F. J. Sladen, F. G. Smith, R. B. U. Somers, A. L. Stuart, T. H. Williams, J. Yatawara, K. E. Ynail.

The Jacksonian Prize for 1933 was awarded to Edgar Samuel John King, F.R.C.S., for his essay on "The Pathology, Diagnosis, and Treatment of Localized Rarefying Changes in Bones, as Illustrated by Perthes's (or Legg's) Disease, Schlatter's Disease, Kummell's Disease, and Allied Diseases." A certificate of honourable mention was awarded

to Mr. H. Jackson Burrows, F.R.C.S., for his essay on this subject. The subject for the Jacksonian Prize for 1935 is "The Pathology, Diagnosis, and Treatment of Intrathoracic New Growths, excluding Neoplasms of the Oesophagus."

The John Hunter Medal, with the triennial prize, was awarded to Dorothy Stuart Russell, M.D., M.R.C.S., for her work on the morbid histology of the kidney and the brain.

The following Members of twenty years' standing were elected to the Fellowship: Professor George Alfred Buckmaster, M.D., George French Stebbing, M.B., B.S.

Examiners in anatomy under the Conjoint Examining Board and for the Fellowship will in future be elected from persons holding a medical qualification registrable in this country. The previous regulation that examiners in anatomy for the Fellowship should be Fellows of the College has been altered as above.

Mr F. M. Stent was appointed assistant secretary to the Examining Board.

After the Council meeting the following cinematograph films were shown in the lecture theatre: (1) a film of ciliary action, made in the College research laboratories, shown by Mr. V. E. Negus; (2) a film made by Sir Charles Ballance and Dr. A. B. Duell illustrating the application of Sir Charles Ballance's experimental work to the treatment of facial paralysis, shown by the conservator of the museum and director of research. [See p. 722.]

The Services

DEATHS IN THE SERVICES

Deputy Inspector-General William Connolly, R.N. (ret.), the oldest living naval officer, died at Kingstown, Dublin, on March 16th, at the great age of 102. He was born on April 11th, 1831, was educated in Dublin, and took the M.R.C.S.I. in 1856 and the M.D. St. Andrews in 1862. He entered the Navy on September 25th, 1856, just at the end of the Crimean War, was promoted to staff surgeon on July 27th, 1867, to fleet surgeon on December 25th, 1878, and retired on April 11th, 1886, with an honorary step of rank as deputy inspector-general. He served on H.M.S. *Calcutta*, flagship, in the China War of 1857-8, attending wounded from the actions at Fatshan and Canton (medal); in the New Zealand War, from July 7th to October 2nd, 1860, as senior medical officer of the Naval Brigade under Commodore Loring and Captain Beauchamp Seymour (medal); and as fleet surgeon of H.M.S. *Euphrates* in the Zulu War of 1879 (medal). He leaves eight children.

Lieut.-Colonel Brisbane Warren Somerville-Large, R.A.M.C. (ret.) died on February 4th, aged 81. He was born at Cork on October 7th, 1852, took the Edinburgh double qualification in 1874, and entered the Army as surgeon on February 4th, 1877, became lieutenant-colonel after twenty years' service and retired on December 20th, 1905. His name was originally only Large; he changed it to Somerville-Large by deed poll in 1887. He served throughout the South African War as P.M.O., first of No. 6 and later of No. 12 General Hospital, took part in operations in the Transvaal, Orange River Colony, and Cape Colony, and received the Queen's medal with three clasps and the King's medal with two clasps. He also rejoined for service in the war of 1914-18, from July 1st, 1915.

Lieut.-Colonel Alfred Edmond Weld, R.A.M.C. (ret.), died in Queen Mary's Hospital, Roehampton, on March 4th, aged 61. He was born on November 30th, 1872, was educated at Charing Cross and took the M.R.C.S. and L.R.C.P. Lond. in 1897. Entering the R.A.M.C. as lieutenant on July 27th, 1898, he became lieutenant-colonel in the long war promotion list on March 1st, 1915 and retired on February 23rd, 1919. He served in the South African War in 1900-2, when he took part in the defence of Ladysmith, and received the Queen's medal with a clasp and the King's medal with two clasps, and also in the war of 1914-18.

Lieut.-Colonel Charles Seaver Smith, R.A.M.C. (ret.), of Edinboro, Manchester, died suddenly at Rhyl on March 7th, aged 59. He was born on November 3rd, 1874, was educated at Birmingham and at Newcastle-on-Tyne, and graduated M.B., B.S. Durh., with first-class honours, in 1897. After serving as house surgeon of the General Hospital, Birmingham, and as clinical assistant at the Royal Orthopaedic Hospital, Birmingham, he entered the R.A.M.C. as lieutenant on December 4th, 1899, became lieutenant-colonel on December 26th, 1917, and retired on half-pay, on account of ill-health, on February 23rd, 1920. He served in the South African War in 1900-1, taking part in operations in the Orange Free State and the Transvaal, including the actions

at Kamee Siding, Vet River, and Zand River, and at Johannesburg; and also in operations on the Zululand frontier of Natal in September-October, 1901; and received the Queen's medal with four clasps. He also served in the war of 1914-18.

Lieut.-Colonel Arthur Henry McNeill Mitchell, R.A.M.C. (ret.), died suddenly of heart failure in London on March 7th, aged 61. He was born on December 16th, 1872, was educated at St. Mary's, and took the M.R.C.S., L.R.C.P. Lond. in 1900. Entering the R.A.M.C. as lieutenant on January 28th, 1901, he became major on October 29th, 1912. He served in the war of 1914-18, and was mentioned in dispatches in the *London Gazette* of January 1st, 1916, and May 29th, 1917. A member of the B.M.A. since 1920, Lieut.-Colonel Mitchell was chairman of the Lambeth Division, 1925-6.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The Financial Statement issued to the House of Commons by Mr. Neville Chamberlain when opening the Budget for 1934-5 on April 17th includes a proposal, which is accepted by the House, to restore, as from July 1st, 1934, on the emoluments of insurance doctors and chemists, one-half of the emergency reductions made in 1931. Restorations in similar proportion are proposed in the emoluments of Ministers, M.P.'s, judges, civil servants, members of the Defence Forces, teachers, and police. In the Budget Mr. Chamberlain also announced a decision to reduce income tax by 6d. in the £, leaving abatements and allowances unchanged. The reduction in the rates of unemployment benefit made in 1931 is to be restored in full as from July 1st if the Unemployment Bill be law by then, and a sum of £3,600,000 is reserved for an increase in transitional payments. As from January 1st, 1935, the present horse-power tax on motor cars will be reduced to 15s. per unit of horse power with a minimum of £4 10s. on a six-horse-power vehicle. Similar reductions will be granted on motor cycles, and the fee of 10s. or 5s. now charged on the surrender of a motor licence will be abolished from August 1st, 1934.

Discussion on the Budget continued during the week in the Commons. The Incitement to Disaffection Bill was read a second time on April 16th, and the second reading of the Shops Bill was set down for that day, but was deferred.

The House of Lords read the Tithe Bill a second time on April 17th.

The Firearms Act (1920) Amendment Bill was put through report stage and read a third time by the House of Commons on April 13th. Its chief purpose is to restrict the sale of firearms to young persons.

The Workmen's Compensation Act (1925) Amendment Bill passed through the House of Commons in committee on April 13th. It dealt with the insurance of persons employed in coal mines. An amendment was inserted to make clear that the scope of the Bill included compensation schemes set up under the principal Act by the Home Secretary in relation to industrial diseases such as silicosis or silicosis accompanied by tuberculosis.

The Supply of Water in Bulk Bill, a Government measure, which has passed through the House of Lords, was read a second time in the Commons on April 11th and put through committee and report stages on April 13th.

The Army and Air Force Bill passed through committee of the House of Commons on April 11th. A proposed new clause to authorize, at the request of parents or guardians, the release from the Army of boys enlisted under the age of 18 was defeated by 264 to 96.

The Gas Undertakings Bill received a second reading in the House of Commons on April 12th.

Road Traffic Bill

In the House of Commons, on April 10th, Mr. OLIVER STANLEY moved the second reading of the Road Traffic Bill. He said he wondered whether the ordinary man realized that between that time (3.30 p.m.) and 11 p.m., when the Speaker would put the question, 180 people would have met with injury on the roads of this country. In the last eighteen months there had been unmistakable signs of a growth in the number of accidents, and because of that they had to survey the field once again. They must all agree that speed reduced the driver's power to deal with the unexpected. It was in the built-up areas that 75 per cent. of the deaths occurred. Pedestrians made up more than half of the people killed on the roads, and about half of the pedestrians were children or old people. This Bill was not a return to the old speed limit, which failed because it did not accord with the view of reasonable people. In regard to tests for drivers, it was true that a certain number of people would be unable to pass the test, some whose physical condition would prevent it, and so on, but the general run of people would eventually pass the test.

A Medical Test

During the debate Sir E. GRAHAM-LITTLE said that he was chiefly concerned with the medical and biological aspect of this problem. It was essentially a medical and pathological problem. The medical profession had had a long experience of accidents. While attention was confined to the mechanical factor progress was slow, but when it was directed to the human factor the improvement was immediate and profound. He urged on the Minister the importance of including a medical test as well as a test of capacity to drive. It was possible at this moment to discriminate between drivers who were likely to be mischievous and those who were likely to be safe. We owed the tests which had been made to advances in medicine, which, as was so often the case, were largely ignored in this country while adopted in others. Some figures published a few weeks ago showed that the practical application of selective tests on drivers of public service vehicles in Paris and in America was not to be ignored. Those figures proved that not only had the rate of accidents been enormously decreased, but that there had been large savings to the companies concerned. He was convinced that advance could best be made by following the progress of scientific medicine. It was not perhaps sufficiently realized by motorists that if, in driving, a decision were taken half a second earlier it might make all the difference between a fatal accident and escape from accident. That was tested carefully among a group of drivers, and it was found that the best driver gained half a second in his reaction compared with the less experienced and less able one. That meant a saving of 30 feet at a speed of thirty-five miles an hour, and the better driver could thus pull up more quickly than the other. A driver's decision could be retarded by a number of innocent causes, such as a heavy dinner, a glass of beer, or fatigue,

No Compensation to Hospitals

Dr. HOWITT urged that the Bill should embody the principles of Lord Moynihan's Road Traffic (Emergency Treatment) Bill. There was, he said, a growing dissatisfaction all over the country that emergency treatment was usually not paid for. It was not fair that emergency cases should be treated, without payment, at hospitals kept up by local voluntary contributions for local needs. Doctors were continually being called to treat emergency cases, for which they were usually not paid, and which disorganized their regular work. Patients in such cases, he thought, were afraid to get into communication with the doctor in order to pay for the treatment because they thought they would put themselves wrong with the law. A very slight increase in the compulsory insurance payment for third-party risk would cover emergency treatment both by doctors and by hospitals.

Mr. SROVEY said that the greatest blot on the Bill was that it did nothing to secure justice for the voluntary hospitals, and left on their shoulders a very heavy burden due to the cost of treatment of road accidents. The Minister of Transport had reminded the House that between the time he was speaking that afternoon and 11 o'clock that night 180 persons would be injured on the roads, but he had not reminded them that those cases would be treated by the hospitals,

which would not be able to recover more than one-half of the cost. In 1931 it was estimated that road accidents still cost the voluntary hospitals of the country £230,000 a year, and that they were only able to recover £34,000. It was true that there were outstanding claims of some £58,000, but anyone who knew how difficult it was to recover those sums would realize that such claims were very doubtful assets indeed. It was very difficult to maintain voluntary hospitals at the present time, particularly in distressed areas, where contributions were made in small sums of 1d. or 2d. a week from working-class people; and it was quite wrong that those who had subscribed this money should have to wait for treatment owing to the pressure on the hospitals due to road accidents. He suggested that a charge should be made on the Road Fund to meet cases of this kind, and that the money should be paid to some central body, which would reconvert the voluntary hospitals for their charges, the hospitals making over to that body any right they might have against any driver who had been proved to be negligent.

Lieut.-Colonel HEADLAN, replying to the debate, said there was no intention of re-establishing a general speed limit for private cars such as existed before 1921. It was, however, perfectly clear that the larger number of accidents taking place at present occurred on built-up areas. So long as that was the case it was desirable to make it less likely that accidents of that kind should occur. The Government thought that by imposing a speed limit in built-up areas no serious hardship would be imposed on motorists. The real point of the Bill was not that the Government hoped by it to do away with all the accidents and troubles on the roads at present, but that its effect would be to reduce accidents and inculcate into the people of the country the necessity for care and caution on the roads. The Minister was ready to consider in committee any suggestions by members for the improvement of the Bill, and matters such as those concerning the hospitals and the doctors could well be considered then.

The Bill was read the second time without a division and sent to a standing committee.

Water Supplies Bill

Sir HILTON YOUNG moved the second reading of the Water Supplies (Exceptional Shortage Orders) Bill in the House of Commons on April 12th. He said that to find a comparable period of drought it was necessary to go back to 1887-8, when, in the twelve months ended March 1st, deficiency of rainfall was 23 per cent. of the normal average; for the twelve months up to the end of March, 1934, it was 27 per cent. The seasonal distribution of rainfall in 1933-4 was bad, with an exceptionally poor fall in the middle and late months of winter. The winter deficiency was six inches of rain, and the March fall no more than average. Reserves of the great towns were so low that measures of conservation were essential. The increasing provision and use of baths cast a new heavy burden on water undertakers, and there was a heavy expansion of industrial requirements. The Rural Water Supplies Act recently passed dealt with rural areas, and was permanent. The present Bill was concerned chiefly with the great urban areas, and was temporary. The Bill proposed procedure by Orders to last for six months, and renewable thereafter, if necessary, during the lifetime of the Bill. It took exceptional powers to tap new sources or by sinking new wells, or by impounding water from streams which there was no present power to impound; to abolish all legal restrictions on the amount of water which could be taken from various sources; and to reduce the amount of compensation water. Water undertakers would receive power to reduce the use of water by a particular customer, or generally. Power would be given for the better apportionment of supplies between undertakers. He hoped much would be done by voluntary effort from water undertakers and the public. The Bill would run till December 31st, 1935. That period would be required for the restoration of deep underground sources.

Mr. ARTHUR GREENWOOD moved a reasoned amendment for the rejection of the Bill, on the ground that the Government had been dilatory. Mr. MACGUISKEN advocated the use in rural areas of steel sheets and tanks to catch and preserve rain-water, as was done in Rhodesia. Sir GOFFREY COLLINS said that there was a water shortage in Scottish burghs and

rural areas. The East and South suffered more. Last summer at least fifty-seven of 195 burghs in Scotland had an insufficient water supply. Coastal towns of Moray and Banff had suffered much for two years from insufficient supplies. Water was taken from streams and chlorinated, but even then the needs of local hospitals could not be properly met. The winter rain of 1933-4 in Scotland had been much below the average. The Departmental Committee appointed last year to inquire into health services in Scotland had recommended an immediate survey of Scottish water resources, and steps were being taken that day to survey the sources and needs. Within the next few days the problem in Fife would be tackled. Mr. McKIE said Scotland had always had a higher consumption of water per head of the population than had other parts of the United Kingdom.

Mr. CHORLTON said the Haweswater scheme would have a capacity of 75,000,000 gallons a day. Were any steps to be taken to complete this reservoir? Manchester and Liverpool had lately connected their water mains. Were other schemes of pooling nearing action? In the Metropolitan Water Board area there would be 12,000,000 people before many years had gone. The present consumption in that area was 280,000,000 gallons. With the population he had named the consumption would be 720,000,000 gallons at 60 gallons a head per day. They should remember that in Scotland the consumption was 100 gallons a head. He hoped the Minister would have a hydrological survey of the country. Lord HARTINGTON said Parliament should hesitate before it upset the provisions which had been made for compensation water, or rivers might become open sewers and menaces of the neighbourhood. Sir FRANCIS FREMANTLE said the daily bath was becoming usual with the growing generation in all classes, but the idea that it was necessary was false. Such frequent baths were comforts and luxuries. Thirty gallons of water per head per day were all that was necessary in an industrial town, and with provision for washing the streets. He was sure that with enlightened application of the provisions of this Bill there would be no serious shortage or real hardship in the towns, but many villages had suffered, and would suffer again, if the drought continued. Mr. SHAKESPEARE said that even up to the day of the debate there was no general shortage of water. The Bill was in ample time to enable undertakers to cope with emergency as it arose. Under the Bill statutory water areas could not be extended, but water could be supplied from one statutory area to another.

The Bill was read a second time by 184 to 23 and sent to a standing committee.

Diseases of Fish Bill

Mr. SKELTON moved the second reading of the Diseases of Fish Bill in the Commons on April 12th. The Bill had passed the House of Lords. He said furunculosis, a virulent and rapidly spreading disease, which particularly affected trout and salmon, had been brought from Europe through the importation of live trout, and made its first serious appearance in this country during the year before the war. In the last few years it had spread rapidly through many salmon rivers in England and Scotland, and in one Scottish river in one year as many salmon were picked up dead with furunculosis as were caught by the net. The first provision of the Bill was for the complete prohibition of the importation into this country of live fish of the salmon species. Secondly, other live freshwater fish and the eggs of any kind of freshwater fish could only be imported by a licensed consignee. The disease also appeared in coarse freshwater fish. Orders could be issued under the Bill by the Ministry of Agriculture in England or by the Secretary of State in Scotland to control or prohibit the transport of live fish out of an infected area, and to provide that any fish farm or private fish hatchery found to be infected by the disease could be ordered to be cleansed and the fish disposed of. Where an area was suspected to be infected a standstill Order could be made for twenty-one days, during which no live fish could be moved out of the area. In a district which was not a suspected area the local fishery board, or any occupier of a fish farm or hatchery or any water, could apply to the Minister for an inspection of the fish to ascertain whether the disease was among them, and the experts from the Ministry would report free of charge. The decision whether an area was infected

lay with the Minister. Sir MERVYN MANNINGHAM-BULLER said it had been proved that in a small hatchery or pool the disease could be cured by the application of salt. Mr. CONANT said there was no known means of eradicating the disease once it got into a stream. Furunculosis could not be determined save by bacteriological examination. Dr. SALTER held that the Bill was not drastic enough. To clean a stream it would have to be cleared of fish and not restocked for two years. A fishpond or hatchery might be cleansed, but would be reinfected if it continued to use water from an infected stream.

The Bill was read a second time without a division, and sent to a standing committee.

Dinitrophenols in the Poison Schedule

Replying to Captain Erskine-Bolst, on April 12th, Sir JOHN GILMOUR said that the steps necessary to add dinitrophenols and dinitrocresols, drugs used for "slimming," to Part I of the existing Poisons Schedule had already been taken, and notice to that effect would appear in the *London Gazette* on April 13th. The statute required that one month should elapse from the date of the notice before the provision came into effect. Sir REGINALD MITCHELL-BANKS, in a supplementary question, asserted that up to April 12th in only one case had death been shown to be attributable to one of these drugs.

Medical Defence Services

Mr. HORE-BELISHA announced in the House of Commons, on April 12th, that agreement had been reached in the consultations with the Government of India regarding the recommendations of the Warren Fisher Committee on the Royal Army Medical Corps and other medical services of the Defence Forces. The Government's decisions on the recommendations of the committee would be announced by the end of April.

Indian Service Pensions.—VISCOUNT FITZALAN OF DERWENT opened a debate in the House of Lords, on April 11th, on the proposals about payment of pensions out of Indian revenue to retired officers of the Indian Army and the various Indian Civil Services. These proposals are contained in the White Paper on the Government of India. Viscount HALIFAX said this subject was engaging the attention of the Joint Select Committee on India. All parties were at one in making these pensions secure. Further discussion would be unprofitable till the Joint Select Committee reported.

Meals to School Children.—In a reply, on April 11th, to Mr. Tom Smith, Mr. RAMSBOTHAM said the effect of school meals on the physical and mental condition of the children was observed by school medical officers, but the arrangements for recording the effect varied considerably from area to area. Answering Mr. McEntee, Mr. Ramsbotham said that, apart from cases discovered at routine medical inspections, children were selected for school meals by special medical examination, by nutrition surveys undertaken by school medical officers, by recommendations of teachers and care committees, and on application by parents. Information about the methods adopted by local education authorities was not complete.

Housing in Scotland.—On April 10th Mr. SKELTON informed Mr. GUY that questions affecting housing in Scotland, including those dealt with in the report of the Scottish Departmental Committee on Housing, were being actively considered in consultation with representatives of local authorities. The Secretary of State for Scotland was not yet in a position to make any statement on the matter. Replying to Mr. Tinker, Mr. SKELTON stated that the number of local authority houses in tenders approved for March, 1934, was for 1,429, the highest since March, 1933. Of these, 1,183, the highest number on record, were for slum clearance houses. Tenders for the erection of houses under Section 3 of the Housing Act of 1923 did not require the approval of the Department of Health for Scotland. One scheme for the giving of guarantees to enable the erection of houses under that section had been submitted, and was now under consideration. Intimation had been received that seventeen local authorities in Scotland were

not prepared to build houses under Section 1 of the Act of 1933 because of the reduction in the amount of the subsidy. Up to date tenders had been approved for the erection by twenty local authorities of 812 houses under the section, and of these, 350 were under construction on March 31st last. Local authorities had power to build houses to relieve overcrowding and to provide for the normal growth of the population, but measures for dealing with the problem of overcrowding in Scotland were at present being considered by the Government in consultation with representatives of local authorities.

Detention in Mental Ward without Certification.—In reply to Mr. Pike, on April 12th, Sir HILTON YOUNG said there was some misapprehension about the facts concerning the death of Mary Medley, a married woman aged 60, of Sheffield. It appeared from the Press report that, on the strength of a medical certificate from the district medical officer describing Mrs. Medley's condition as "bronchitis and unsound mind," she was removed by the general relieving officer to the hospital under the provisions of Section 20 of the Lunacy Act with a view to being kept under observation in the mental ward. The patient died there before any question of further formal proceedings for certification under the Lunacy Act arose, and she was never certified. In these circumstances there was no case for inquiry into the operation of the Lunacy Act. He could not accept the suggestion that, in view of the present circumstances, which permitted an officer of a public assistance committee to issue an order for detention in a mental ward, no person should be admitted as a mental case until there had been a thorough medical inquiry and the mental condition of the person had been established. In this particular case there was no question of certification.

Appointment of Matron to Army Headquarters, India.—On April 16th Sir SAMUEL HOARE told Dr. O'Donovan that members of both the British and the Indian nursing services were eligible for appointment to the post of chief principal matron at Army Headquarters, India. The appointment was made on the merits of the candidates from either source on each occasion.

The Small-pox Outbreak at Blackburn.—Replying to Mr. Groves, on April 17th, Sir HILTON YOUNG said that he was advised that the recent outbreak of small-pox in Blackburn was an outbreak of variola major. Answering another question by Mr. Groves, the Minister said that four of the early cases were originally diagnosed as chicken-pox. It was not proposed to take proceedings against the medical attendant or attendants concerned for failing to notify these cases as small-pox. An error in diagnosis did not constitute an offence under the Infectious Disease (Notification) Acts. He was aware that the first case which led to the outbreak at Blackburn was that of a man employed at a cotton mill, where he handled cotton daily. He had no satisfactory evidence whether the man contracted the disease in the performance of his duties.

Unemployed not Entitled to Medical Benefit.—Sir HILTON YOUNG informed Mr. Thorne, on April 17th, that the returns which had now been received from approved societies indicated that approximately 125,000 members, who after a period of prolonged unemployment were continued in insurance in 1933 under Section 1 (5) of the National Health and Contributory Pensions Act, 1932, had ceased to be entitled to medical benefit on December 31st last, though continuing to be insured for pensions purposes. That number, however, would be substantially reduced by reinstatements to medical benefit, notifications of which were now being received from the societies at the rate of several hundreds a week.

Notes in Brief

Sir John Gilmour is making inquiries with a view to deciding whether the safety of film-containers should be dealt with by regulation.

Mr. Ramsbotham told Mr. Anstruther-Gray, on April 12th, that memoranda had been issued by the Board of Education to local education authorities from time to time on the subject of traffic dangers, and useful work in training children how to avoid these dangers was being carried on in the schools by local authorities and teachers in co-operation with the National Safety First Association.

Medical News

A special general meeting of the Fellows of the Royal Society of Medicine will be held at 1, Wimpole Street, W., on Tuesday, May 1st, at 8 p.m., when Dr. Russell Reynolds will give a demonstration on x-ray cinematography, and Dr. Robert Janker (Bonn) will also show films. Admission will be by ticket only, applications for which should be addressed to the secretary.

At the next monthly clinical meeting for medical practitioners, at the Hospital for Epilepsy and Paralysis, Maida Vale, W.9, on Thursday, April 26th, at 3 o'clock, Dr. Blake Pritchard will give a demonstration. Tea will be provided, and those intending to be present are asked to send a card to the secretary.

At the next scientific meeting of the Zoological Society of London, on Tuesday, April 24th, at 5.30 p.m., the secretary, Sir P. Chalmers Mitchell, F.R.S., will report on the additions to the society's menagerie during March, 1934, and Colonel A. E. Hamerton, R.A.M.C. (ret.), will present a report on the deaths occurring in the society's gardens during the year 1933.

The spring meeting of the Dutch Society of the History of Medicine, Natural Sciences, and Mathematics will be held at Leyden on April 28th and 29th, when papers will be read on old microtomes, Cosmas and Damian, Jan Steen and the doctors, and the views of the South American Indians on diseases and their treatment.

A meeting of the Fever Group of the Society of Medical Officers of Health will be held at 1, Upper Montague Street, W.C., on Friday, April 27th, at 5 p.m., when a discussion will be opened by Drs. C. D. Agassiz, G. Jessel, and J. E. McCartney, on the relation of measles and whooping-cough to chronic inflammatory conditions of the chest. The clinical, radiological, and pathological aspects of the subject will be dealt with, and all medical practitioners interested are invited to be present.

An exhibition entitled "India," by Lieut.-Colonel F. D. S. Fayrer, I.M.S. (ret.), will be on view at the galleries of the Royal Photographic Society, 33, Russell Square, W.C.1, from May 3rd to 31st.

A course of lectures on pathological research in its relation to medicine, to be given on Thursdays, at 5 p.m., during the summer session, commenced at the Institute of Pathology and Research, St. Mary's Hospital, Paddington, on April 19th, when Professor A. Bethe, director of the Institute of Physiology, University of Frankfurt/M., lectured on permeability and osmoregulation in lower animals. The lectures are open to all members of the medical profession and students in medical schools, without fee.

A post-graduate course commenced at the Dundee Royal Infirmary on April 12th, and will be continued on Thursdays, at 3.15 p.m., until May 24th. No fees will be charged for the lectures and demonstrations, but there will be a registration fee of £1 1s. to cover expenses of printing, etc. Tea will be provided at 4 p.m.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that Dr. Clark-Kennedy will lecture on cardiac irregularity, at 11, Chandos Street, on April 24th, at 2.30 p.m. The fifteenth lecture-demonstration, on May 1st, will deal with auricular fibrillation. Dr. Ellman will conclude his series of lectures on chronic diseases of the chest on April 25th and 27th. The second lecture, in the series arranged for Thursdays, will be given by Mr. E. A. Peters on "Septic Tonsils—Nasopharyngitis and its Results," on April 26th, at 4 p.m. These lectures are open to all members of the medical profession, and are free to members and associates of the Fellowship. The Samaritan Hospital for Women is holding a week-end course on April 28th and 29th. Other forthcoming courses include: psychological medicine at the Maudsley Hospital, April 30th to June 1st; dermatology at St. John's Hospital, April 30th to June 2nd; a week-end course in cardiology at the Victoria Park Hospital, May 5th and 6th; advanced urology at St. Peter's Hospital, May 7th to 19th.

A complimentary dinner to Mr. R. H. Burne, F.R.S., late physiological curator at the Royal College of Surgeons of England, will be held on Thursday, May 10th, at 7.30 p.m. for 8 o'clock, in the Langham Hotel, Portland Place, W. The honorary secretary to the committee is Dr. John Beattie, Conservator of the College Museum.

The Vienna Medical Faculty has arranged a post-graduate course on recent advances in therapeutics, from May 28th to June 10th. The fee is 50 schillings. Further information can be obtained from Dr. A. Kronfeld, Porzellangasse, 22, Wien 9

We are informed by the Swiss Legation (18, Montagu Place, Bryanston Square, W.1) that a post-graduate course, under the auspices of the International Hospital Association at Lucerne and the Swiss Hospital Association at Bern, will be held in Switzerland this year from August 15th to 23rd, and will be followed by a tour of the hospitals in the Canton of Grisons. Certain facilities already granted will much reduce the cost of the visit. Application for particulars of the course should be made to Veska-Bureau, Obergrundstrasse 13, Lucerne.

At the annual dinner of the Margate Chamber of Commerce on April 26th, in St. George's Hotel, Cliftonville, the principal guest will be Sir Henry Gauvain.

The London Fever Hospital, Liverpool Road, Islington, N.1, announces in our advertisement pages that a limited supply of convalescent measles serum is available for general practitioners for the protection of babies and young children. Application should be made to the resident medical officer. We are asked to add that the hospital committee urgently needs volunteers from among convalescent measles patients who would be prepared to attend and have blood taken for the purpose of preparing serum.

The annual dinner of the Metropolitan Police Surgeons' Association will be held at 7.30 p.m. on Thursday, May 3rd, at the Holborn Restaurant. Among the numerous guests to be received by the president, Dr. Mayberry, will be Lord Trenchard, the Commissioner of the Metropolitan Police.

The present president of the North of England Branch of the British Medical Association is Dr. Archibald Fairlie of Blyth, and at the annual meeting and dinner of the Blyth Division, held on April 12th, Dr. C. F. Fairlie—his son—was elected chairman of the Blyth Division. It would be interesting to know if it has ever before happened in the history of the Association that a son held office as chairman of a Division in the Branch of which his father was at the same time president.

The Council of the Royal Institute of Public Health, having received invitations from the universities and municipalities of the cities of Danzig, Warsaw, Cracow, and Gdynia, has decided to organize a medical educational tour to Poland. The arrangements for this journey up to the present are that the party shall leave London on Thursday, August 2nd, by s.s. *Baltonia*, and go via the Kiel Canal to Danzig; thence by train to Inowroclaw, Warsaw, Cracow, Gdynia, and Zoppot, arriving back in London on August 13th or 14th. The universities and municipalities concerned are arranging certain functions, hospitality, etc., the inclusive cost of the tour being 18 guineas. As the cabin accommodation on the boat is somewhat limited, early application for reservation of berths is necessary. Full details of this tour can be obtained from the secretary, Royal Institute of Public Health, 23, Queen Square, W.C.1.

The Registrar of the General Medical Council informs us that voting papers in connexion with the election of a Direct Representative were issued on Wednesday, April 17th, to all practitioners having registered addresses in England and Wales. Any such practitioner who has not received a voting paper, whether he wishes to vote in the election or not, should immediately communicate with the office of the Council, 44, Hallam Street, Portland Place, London, W.1, in order to ascertain that his address is correctly entered in the *Medical Register*.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Aitology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumbeuch Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

"A Terrifying Yell"

Dr. W. PATERSON BROWN (London, W.) writes: The interesting case described by "J. F." (p. 697) is probably one of Gilles de la Tourette's syndrome, a form of psychical and motor tic. I have seen two similar cases within the last year. Typically there is an involuntary explosive utterance, usually of some obscene word, to the accompaniment of some tic movement, often generalized in nature. In my cases the explosive utterance bore a marked resemblance to the barking of a dog, but in one of them the bark might be replaced by the word *bur*, in which form the tic commenced. While remissions are not uncommon, there is a tendency for the illness to proceed to dementia. Psychological treatment probably offers the best chance of a cure. Peripheral irritation is rare in its aetiology, and general medical measures are usually less effective than in simple tics. However, a measure of relief usually results from the removal of environmental stress and the provision for constant active occupation. One of my cases was greatly helped by the removal from home to a sympathetic but understanding environment. Unfortunately I was prevented from treating either of my cases psychologically, as I should have liked to do.

"G. B." writes to suggest that "J. F." would do well to get his patient into touch with the Manchester Child Guidance Clinic, at 292, Oxford Road.

Intravenous HCl

Dr. A. C. GREENE (Sutton, Surrey) writes: I wish to inquire if any medical men in this country have tried the intravenous injection of hydrochloric acid in dilution of 1 in 1,500 and 1 in 1,000. I understand it has been used and is being used extensively in the U.S.A. for all manner of complaints, and with beneficial results. It was first practised by a Dr. Barr Ferguson of Birmingham, Alabama. He claims that hydrochloric acid solution injected intravenously increases cellular activity and repairs tissue as a result of artificial stimulation of the white cells. He found that in all manner of infections, from syphilis to coryza, he obtained clinical results which he could attribute only to the increased cellular activity following the injections. Following these injections a decided increase in the number of white cells occurred, and the expected clinical results were obtained. His claim that the results seen in the use of the "specifics" were attributable to no selective action of the drug, but to the power of arsenic, quinine, or mercury in stimulating the numbers and activity of the white blood cells, seems worthy of consideration, and perhaps of clinical application. Therapeutic measures—for example, mustard plasters, liniments, and other counter-irritants—exhibit their undoubted remedial effects because of stimulation of the white blood cells and the following phagocytic activity. Since it is a generally accepted fact that phagocytosis is

a most consistent and essential factor in resistance I feel that any agent that stimulates these cells would be useful, and it would therefore be most interesting to have the views of those who may have tried the intravenous injection of hydrochloric acid in 1 in 1,000 solution.

Silvester of Silvester's Method

Dr. M. BINGEN (Mathias Wynandsstraas, 6, Maastricht, Holland) inquired in our issue of February 3rd where he could obtain a portrait of Dr. Henry Robert Silvester (1828-1908), whose name has long been associated with a method of resuscitating stillborn children and of restoring persons apparently drowned or dead. We now learn from Dr. Bingen that he has obtained a portrait of Silvester through the good offices of Dr. John S. Clarke of Weobley, Herefordshire.

Income Tax

Repayment on Allowances

"WINNER" has an unearned income of £310 (gross) taxed by deduction, presumably at the standard rate, and his wife £5. They pay £103 in life assurance premiums, and he shares with his brother the support of his mother. What repayment can he claim?

* Repayment is apparently due as follows:

Personal allowance (£150 at 5s.)	...	£37 10 0
Reduced rate relief (£165 at 2s. 6d.)	...	20 12 6
Life assurance relief (£52 10s. at 2s. 6d.)	...	6 11 3
Dependent relative relief (£12 10s. at 2s. 6d.)	...	1 11 3
		£66 5 0

The relief in respect of life assurance is restricted to tax on one-sixth the total income of £315; that in respect of a dependent relative to one-half the statutory allowance of £25.

Appointment—Car Expenses

"H. C." holds an appointment under a county council; he is required to maintain a car and receives a mileage allowance. He bought a car for £265 in 1928 and sold it in 1933 for £20, when he bought a new car for £213. What can he claim?

* The replacement cost is, of course, £213 - £20 = £193, but he will have to overcome the difficulty that he receives an allowance for his car expenses, which will, *prima facie*, be regarded as sufficient. The income tax deduction is restricted to the expenditure incurred "wholly, necessarily, and exclusively" in carrying out his duties, and the income tax authorities are likely to place on him the onus of showing that the county allowance does not reach the "necessary" standard.

Car Allowance

"C. H. D." runs two cars, and for many years has spent regularly £100 a year on changes. He is allowed wear-and-tear at the rate of 15 per cent. of the written-down value, usually between £30 and £50, so that he appears to lose on the arrangement.

* There seem to be two alternatives: (1) to drop the depreciation claim and claim the annual cost of renewal instead; and (2) to claim the obsolescence allowance in addition to the wear-and-tear allowance. The latter would amount to the excess of the cost of the "change" over the aggregate amount of the wear-and-tear allowance made for the car exchanged, and can be claimed for the six previous years. Obviously that form of claim is preferable, but there may be some difficulty in persuading the authorities that cars regularly exchanged after only two years' running are in any real sense "obsolete." "C. H. D.," however, has equity on his side, and it might be well worth while trying the claim.

Assistant—House Rent Paid

"W. W." is assistant to a firm which pays him £500 a year, and also pays the rent (£50) of a house in which he lives, and on which he pays the rates. Is the £50 assessable?

* "W. W." is evidently occupier of the house, and enjoys the use of the house to the value of £50. If he is responsible for the rent then the payment by the firm is equivalent to payment by him; on the other hand, if the firm is only responsible for the rent, and requires him as part of the conditions of his employment to reside in the house in question, then we are of opinion that he is not liable.

LETTERS, NOTES, ETC.

William Harvey's Gout

Dr. KENNETH J. FRANKLIN (Oriel College, Oxford) writes: In your very generous review of my *Short History of Physiology* in the *Journal* of April 14th, you say that for some reason I assume that Harvey suffered as a young man from gout. I write to give my authority for the suggestion, which is Sir Thomas Barlow's *Harveian Oration*, 1916 (*Lancet*, October 28th, 1916, p. 740).

"Periodical Sterility"

"X" writes: My experience of this form of contraception is totally at variance with that of the correspondent in your issue of April 14th. I have been married for fourteen years, and in medical practice for fifteen years. During this time I have known every one of the methods of contraception now advocated fail both in my own personal experience and in that of patients and friends who have confided in me. On the other hand, I have never known the method of "periodical sterility" as advocated by Ogino fail. Its success depends on two essential requirements—namely: (a) that the menstrual cycle must be a regular twenty-eight-day cycle; (b) that due care is taken to count backwards for ten days from the date on which the next menstruation is due. Thus, although obviously incapable of general application, the method can, in my view, be recommended without hesitation and with absolute confidence to those with regular twenty-eight-day cycles. In my own married life the method has been unfailingly successful since its adoption after several pregnancies. Since then conception has occurred only following coitus deliberately planned to take place during the period of ovulation, and then only. For easy reference I append the dates of ovulation and sterility according to Ogino:

Medical Golf

The Milsom Rees Challenge Cup will be played for by members of the Medical Golfing Society on Wednesday, April 25th, on the links of the Kingswood Golf Club. Members are requested to send in their entries by April 23rd. The semi-finals of the knock-out tournament are between Dr. D. S. Gordon and Dr. Bletsoe, and Dr. Glyn Hughes and Dr. May.

Boots Pure Drug Co. (Nottingham) have prepared for the information of members of the medical profession two new booklets. One is on medicinal glucose (anhydrous), a white crystalline powder conforming to the requirements of the *British Pharmacopoeia*, 1932, for dextrose. The other is on gonococcus vaccines prepared in the department for venereal diseases at St. Thomas's Hospital and issued under licence from the Ministry of Health. Each booklet is furnished with references to recent medical literature.

From April 23rd the address of the West End depot of Crookes' Laboratories (British Colloids Ltd.) will be 88, Newman Street, W.1. Telephone number as before; Museum 3663.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 46, 47, 48, 49, 52, 53, and 54 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 50 and 51. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 212.

A British Medical Association Lecture

ON

AURAL DISCHARGES: THEIR SIGNIFICANCE AND TREATMENT*

BY

JOHN F. O'MALLEY, F.R.C.S.

CONSULTING SURGEON EAR, NOSE, AND THROAT DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL; LATE PRESIDENT, SECTION OF OTOTOLOGY, ROYAL SOCIETY OF MEDICINE

The subject of this lecture embraces a very large section of the common diseases of the ear, so that of necessity, in the time at my disposal, I can only deal with the salient points. This is probably not a matter for regret, as an attempt to crowd into it a great amount of detail would detract from its clarity and usefulness.

All discharges escaping from the external auditory meatus are pathological in origin, with the exception of cerumen, although this may possibly become so when it is excessive or impacted. They may have as their primary source the pinna, external meatus, middle ear, mastoid antrum or cells, or even the intracranial cavity. They generally have certain characteristics, which enable us to make a useful classification of them as set forth below. These characteristics, if carefully elicited in taking the history of the case, possess considerable value, in that they often indicate the nature of the disease and so form the first pointer towards a correct diagnosis.

Classification of Aural Discharge

I Watery	Colourless or not Scanty Copious Sticky, mucoid, or viscid Odorous or not	1. Middle-ear catarrh with perforated drum
			2. Cerebro-spinal fluid
II Purulent	Whitish Yellow Scanty Copious Sticky, mucoid, or viscid	3. Meatal eczema
			1. Furunculosis
III Haemorrhagic	- - -	Watery sanious fluid— Scanty Copious Blood	2. Acute middle-ear suppuration
			3. Chronic middle-ear suppuration
IV Cerebromucous	Solid Semi-solid	4. Foreign body
			1. Injury
			2. Acute influenzal inflammation of the middle ear
			3. Granulation tissue, polyp, etc.
			4. Epithelioma of the external meatus

Aural discharges are always objective evidence of disease, and in some instances are associated with the most serious affections of the ear, which may lead to complications endangering life and to the temporary or permanent loss of hearing.

WATERY DISCHARGES

There are three possible causes of watery discharges from the ear:

1. The early stage of a middle-ear catarrh accompanying a nasal coryza, in an ear with a large perforation in, or the absence of, a tympanic membrane. This occurs in such cases frequently, but it is usually overlooked unless it passes into the purulent stage.
2. Escape of cerebro-spinal fluid. This is exceedingly rare, and can only occur following a trauma.
3. Associated with acute meatal eczema. This is fairly common.

In the first the fluid is colourless, very scanty, odourless, and sticky. It is similar to the efflux in the early stage of a common cold, but it may later become purulent and yellow.

The second is very rare. In relation to fractures of the base of the skull the discharge is usually blood-stained at first, then becoming quite clear, but this will be mentioned under another heading. I have seen one case of clear, watery discharge (cerebro-spinal fluid) in a soldier in 1918. Its escape was a sequence to an old radical mastoid operation, performed ten years before and followed on three later occasions by the removal of a polypus. It continued to escape for over twelve months, gave the characteristic tests, and the quantity lost was estimated to be $1\frac{1}{2}$ gallons in three months or about 6 gallons for a year. I showed the case at the Section of Otology in August, 1918, and none of the members present had ever seen one of such long duration and severity.

In the third—acute eczema—the quantity varies from scanty to moderately copious. It may stand out in beads on the affected surface. It is clear, sticky, and usually odourless, though it may be offensive if much decomposed: epithelium remains *in situ*. It is invariably preceded by itchy sensations, followed by some degree of pain and local tenderness, but with practically no interference with hearing, unless there is much swelling. The stickiness of the discharge is characteristic of acute eczema, and wool or lint will adhere to the surface of the ear if applied to it. It is not, however, stringy like discharges containing mucus.

PURULENT DISCHARGES

There are three common causes of purulent discharges from the ear:

1. Furunculosis of the external meatus.
2. Acute middle-ear suppuration.
3. Chronic middle-ear suppuration.
4. Foreign body (in a child's ear—not common).

In furunculosis the discharge is scanty, yellowish, not sticky, and usually odourless. It is always preceded by local pain and tenderness in the external meatus, which may in some cases be very intense, and in such cases, owing to an associated perichondritic swelling, the hearing is impaired. This is the commonest inflammatory disease of the external meatus.

In acute middle-ear suppuration the discharge is often copious, of a bluish whiteness, very sticky, and mucoid and odourless. Its stickiness is pathognomonic of its origin, as having come from an inflamed mucous membrane surface, and therefore from the middle-ear cavity. This physical characteristic can be easily demonstrated by mopping out a portion of the contents of the external meatus with a rolled pledget of wool and then applying the pus-moistened wool to some other object and withdrawing them slowly apart, when strings of mucus will be seen. This proves the source of the pus, even where a perforation of the drum membrane may not be visible, and differentiates it from pus of furuncular origin, which never contains mucus, unless in the much rarer instances where both meatus and middle ear are involved simultaneously. This discharge has invariably been preceded by an acute febrile affection of the upper airway and pain deep in the ear; no local meatal tenderness, but deafness is marked. The degree of pain preceding it, in infants,

* Delivered to the South Suffolk Division of the British Medical Association on December 1st, 1933.

is often negligible, probably owing to the anatomical characteristics of their Eustachian tubes, the latter being straight and short, with a relatively large lumen, which permits the release of tension in the middle ear during the acute stage. The ear affection in these cases is usually a sequence of pharyngeal sepsis associated with teething troubles. Infants with irritation of the gums show an extraordinary predilection for biting on any available object, a proceeding most likely to cause an oral sepsis, with its possible extension to the nasopharynx.

Variation in the quantity of discharge of a recent middle-ear suppuration may have special significance. As the inflammatory manifestations, such as pyrexia, pain, and intensity of deafness, subside and pass off, the quantity of the discharge gradually lessens and becomes less viscid; but should the flow increase again and become relatively copious an abscess of the mastoid must be suspected, although there may be no localizing swelling or tenderness in the latter region. This is a fairly common sequence of events, and at once its observance raises the question of an operation for mastoiditis.

In chronic middle-ear suppuration the discharge is invariably scanty and yellow, and shows practically no stickiness, unless associated at the moment with a recent inflammatory recrudescence of the middle-ear cavity and Eustachian tube. It is often malodorous, if the case is of long standing, due to the presence of fatty acid degenerative products of dead epithelium and pus. The malodour is especially suspicious of the condition known as cholesteatoma, where masses of suppurating epithelial debris are present in the attic, aditus, or mastoid antrum, and, when large, cause varying degrees of erosion of bone. These erosions may open the path to the invasion of the labyrinth or cranial cavity and lead to the most serious complications which are possible to occur in diseases of the ear.

A discharge from one ear in a child, if of recent onset and not related to any illness, should raise the suspicion of a foreign body.

HAEMORRHAGIC DISCHARGES

There are at least four possible causes of haemorrhagic discharge from the ears:

1. Injury (blood, cerebro-spinal fluid).
2. Acute influenzal inflammation of the middle ear.
3. Granulation tissue, polyp, or ulceration of the middle ear, and caries of bone.
4. Epithelioma of the external meatus.

If the discharge is the result of a blow on the ear or the result of gunfire or shell explosion or high diving, pure blood usually escapes first, becoming serous later. It is rarely profuse. If the injury is considerable, as in a motor accident, causing fracture of the base of the skull, the escape of pure blood is sometimes accompanied by a considerable amount of thin, sanious fluid, which raises the suspicion of its being cerebro-spinal in origin. After bleeding has ceased it may continue to escape as a clear fluid dripping from the lobe of the ear, when it can be collected in a test tube and examined for its chemical properties, etc., to establish its nature. It is significant of a severe lesion, and increases the gravity of the prognosis, but is not necessarily a fatal complication, nor does it appear to increase the risks of meningitis arising in such cases. Areas bathed in cerebro-spinal fluid do, however, appear to become septic with greater facility than in its absence.

In acute influenzal middle-ear inflammation the discharge may appear to be pure blood, but is more often blood-stained serum and small in amount. This fluid invariably escapes from a burst haemorrhagic bulla, which had formed on the outer aspect of the tympanic membrane or adjacent meatal wall, and is almost pathognomonic of

an acute influenzal middle-ear infection of the *Streptococcus haemolyticus* type. It appears early in the acute inflammatory involvement of the middle ear, is indicative of an intense infection, and usually precedes the formation of pus by a couple of days, and is accompanied by pyrexia, pain, and deafness in the affected ear.

In the polypoid type of case, the discharge is either pure blood or pus and blood, usually small in amount, but a drachm or more may escape. There is a history of chronic ear trouble, with a probable recent increase in deafness owing to enlargement of the polypus or granulation tissue, but there is rarely any pain or pyrexia. Its occurrence may follow a slight injury, and its appearance signifies the presence of a polypus or granulations, growing on an ulcerated area of mucous membrane or bone. The tympanic bony ring is intensely hard, and hence badly supplied with blood vessels. It is therefore very prone to caries and shows poor tendency to repair in consequence of its defective nutrition, and this is the chief cause of chronicity. The granulations formed in the attempt at healing are flabby and unhealthy, and therefore apt to bleed easily on touch. The pedunculated polypus usually grows from the middle-ear mucous membrane, is covered with epithelium, is firmer in structure, and unless large enough to extend well outwards in the meatus, is less liable to bleed on slight trauma than the softer granulations.

The fourth type of source, epithelioma, is rare, but sufficiently common to warrant its suspicion when blood escapes from an ear, with no immediate history of an injury or disease, in a person well over 50 years of age. Granulations on an epitheliomatous ulcer are exceedingly friable, and liable to bleed on slight trauma.

CERUMINOUS DISCHARGE

Anxious mothers frequently consult a doctor on finding a little cerumen in an infant's ear. It may have some significance at teething time. Irritation of the gums may cause reflex discomfort, which induces the child to rub the ears. The frequent repetition of this will excite the glands to greater activity in the production of more cerumen.

More commonly the middle-ear discomfort is an infection from the nasopharynx, the result of spread from oral sepsis. The rate of ceruminous secretion in adults seems to vary with the individual, though it is not governed by any physiological law of which I am aware, but its accumulation, however, is largely conditioned by the anatomical formation of the external meatus. If the posterior portion of the outer end of the meatus is overhung by the free border of the concha, the secreted wax tends to be pushed deeper in the meatus, rather than extruded, by the movement of the lower jaw, as should take place normally. It may completely occlude the meatus, causing deafness, and if long retained may set up a dermatitis, accompanied by some pain and discharge.

TREATMENT

It is my intention, owing to considerations of time and space, to limit treatment to one proven method, to the merits of which I can testify, rather than discuss alternative ones which are equally well recommended in the textbooks.

The watery aural discharge from an open middle-ear cavity, resulting from a coryzal extension, usually subsides with the exciting cause in the nose and Eustachian tube, and rarely requires any special treatment. A clean piece of wool, changed when even slightly moist, but at least night and morning, prevents discomfort from the discharge, and lessens the risk of an added infection through the external meatus. If the discharge becomes

purulent and persists when the cold in the head has disappeared, special treatment is indicated, to obviate its passing into a chronic condition.

I favour dry treatment in such a case, and have found the daily insertion of boric powder iodized to the extent of 1 per cent. or even less to give excellent results. If it should still persist after a fortnight's treatment, slight ulceration of the mucous membrane and the formation of some granulation tissue is possibly present. To ascertain this, syringe clean with warm boric lotion, dry, and look for a granulating spot. If found, roll a thin piece of wool on an applicator, dip it in 5 per cent. silver nitrate solution, and apply under direct vision firmly to the area, one day a week, using the powder the other six. I have found the result of this line of treatment in any form of chronic middle-ear discharge most gratifying, and will refer to it again later in more detail.

Apart from fractures of the base of the skull the escape of cerebro-spinal fluid from the ear is, as I have already pointed out, an exceedingly rare occurrence.

I reopened the mastoid in my case and packed it in the usual way with gauze and bipp. In twenty-four hours the dressing was soaked with pus. This occurred on three consecutive days, and still the mastoid cavity and wound continued to pour out pus. I then ceased to pack, but cleaned up with 40 per cent. spirit, using a little gauze soaked in this as a drain, with gratifying results. It cleared up, and later, when granulations had formed, I packed them firmly against the fissured area (junction of attic and aditus), which eventually converted them into a sound scar.

Acute eczema of the ear responds well to treatment. At this stage the affection has usually extended from the meatus to the pinna, and is accompanied by considerable weeping. The application of calamine lotion by dabbing it on with a piece of cotton-wool soothes and helps to dry the affected area in a few days. The following is then used until all weeping has ceased and the condition has passed into a scaly stage: Lassar's paste (zinc oxide, pulv. amyli, lanoline, and vaseline, each 2 drachms) spread on lint (smooth side) and applied night and morning. To treat the scaly stage add 10 grains of salicylic acid to the ounce of Lassar's paste and smear on daily, leaving the part uncovered. If the ointment is warmed to soften it, by standing the pot in hot water, it can be applied with a camel-hair brush. Eczema of the ear in either the wet or dry stage is accompanied by seborrhoea of the scalp, as indicated by the presence of more or less dandruff. Many dermatologists regard the ear condition as a seborrhoea also, and secondary to the scalp. The point of importance, however, is that the scalp and ear must be treated simultaneously to be really effective. The scalp should be shampooed twice a week for two or three weeks, taking care to protect the ear from the shampoo liquid and water. Soap spirit (sapo mollis and spirit. vini rect. each 2 ounces), 1 drachm of which, if rubbed into the scalp, acts well, but it should be thoroughly removed by repeated rinsing with water. In less acute cases with very little discharge, and if confined to the meatus, the following is a useful application:

R Ung. hydrarg. nit. dil.	1 drachm
Liq. carbonis deterg.	10 minims
Paraffin. liquid.	1 ounce

Apply with a camel-hair brush night and morning.

In the discharging stage of furunculosis of the ear, filling the meatus lightly with a strip of half-inch ribbon gauze, smeared with 10 per cent. ichthyol in glycerin, once a day, is an excellent method of treatment. The mental epithelium is thus kept clean, dry, and protected from maceration, the latter being the greatest factor favouring recurrence in these cases.

ACUTE MIDDLE-EAR SUPPURATION

The treatment should be general and local, the former being often the more important. The ear condition is always secondary and invariably due to some upper respiratory infection of an exanthematous or influenzal type, so that the first consideration in the treatment is that of the primary affection.

With the onset of an aural discharge, the middle-ear symptoms become less intense, pain should have passed off by the release of inflammatory tension, and any pyrexia specially excited by this complication should have subsided or nearly so. During the acute pyrexial stage the patient should remain in bed, and after this has subsided with the onset of the discharge, confinement to the house or sickroom is indicated so long as the discharge shows much viscosity. This physical character indicates the presence of much mucus, and the latter is evidence of the existence still of marked inflammatory engorgement in the middle ear and Eustachian tube, upon which a relapse with complications may easily supervene.

If the case is "hanging fire" and does not make steady progress to recovery, as when the discharge, though free, is still very viscid and some pyrexia exists, a 10 c.cm. injection of "anti-scarlet-fever serum"—concentrated streptococcus antitoxin (scarlatina) globulins (B.W. and Co.)—will often give a decided turn for the better. It seems to aid or rouse the flagging efforts of the body's immunizing reaction to the infection, and as it is to this reaction we must look as the first line of defence and attack, our usefulness lies chiefly in doing everything which favours its maximum effectiveness, whilst at the same time watching for any threatened complications. Keeping the patient indoors and free from exposure to chills and fresh infection is conducive to this purpose.

Local treatment consists in keeping the ear clean, and if possible free from infection from without by an invasion of the more resistant organisms such as staphylococci and its common sequence, the conversion of an acute into a chronic middle-ear suppuration. For this reason I do not advocate the use of hydrogen peroxide, as it causes too much commotion when mixed with pus, and is liable to carry the contents of the meatus—organisms or otherwise—through the perforation into the middle ear. Syringing may do the same if used with force. Wiping away the pus with wool, dry or soaked in bicarbonate of soda or boric acid solution, will cleanse it, and then filling the meatus with glycerin, acid. carbolic, 2 per cent. will render it practically antiseptic. Covering the area with a sterile dressing to be changed at least night and morning is also helpful. Drainage of the middle ear does not depend on the removal of secretion from the external meatus provided it is not dammed back by plugs of wool. The entrance of air into the middle ear through the Eustachian tube, when we swallow or blow the nose, expels pus through the perforation, and is the most effective factor in drainage. When the discharge has become thinner, filling the meatus daily with boric powder iodized to 1 per cent. is most effective. The boric powder is absorbent, hygroscopic, and antiseptic, and the presence of heat and moisture causes the liberation of some nascent iodine, increasing the degree and efficiency of the antiseptics.

CHRONIC MIDDLE-EAR DISCHARGES

Cases which belong to this category present the most difficult and serious problems of all aural affections—difficult because of their disappointing resistance to any line of treatment which the patient or a nurse can carry out, and serious because of the dangerous possibilities to life which accompany them. For these reasons I propose to deal with the treatment at some length. I must, however, digress at this point to examine certain factors concerned

in the health and infection of air-containing cavities associated with the respiratory tract, because a clearer conception of these should enhance our chance of success in treatment.

I have personally formed certain views on the physiological and pathological problems of air spaces which are either in constant or intermittent continuity with respiratory air currents through the nose and nasopharynx. These are based upon certain researches carried out during the past few years, chiefly upon the nasal accessory sinuses, but also upon the ear. I think it will prove correct to assume that certain principles can be seen to underlie the cause for the maintenance in health of an air space under normal conditions, its spontaneous cure from an inflammatory affection or why it persists in a diseased state. It is briefly summed up in the word "ventilation." This implies the free entrance and exit of air, due to synchronizing air-pressure variations between the air spaces and the respiratory passages, during inspiration and expiration, and so long as this is possible the drainage and removal of certain secretions will be possible also. This state obtains throughout the healthy period of the cavity; it is suspended in diseased conditions, which may prove only temporary, because it is again re-established spontaneously, but the disease remains permanent if it is not, and this is the stage at which the attention of the surgeon is called for. The principles which apply to nasal accessory sinuses are also with slight modification applicable to the middle-ear space. In the former the air movements in the cavity and respiratory passages are practically continuous, whilst in the latter they are intermittent. In the former the walls are rigid and fixed, but in the latter one boundary is membranous and mobile, facilitating the temporary increase or diminution of its contents, whether of air or fluid.

A large number of middle-ear inflammations never suppurate, a second large class suppurate but do not perforate, a third large proportion do all three, and yet all of them heal spontaneously, whilst a fourth residuum goes through the same pathological phases and remains chronically diseased. In the first two the air exchange between the middle-ear cavity and respiratory movements remained possible during the attack, in the third they are not so temporarily, but the membranous walls yielded to infection and pressure of secretion, to be followed by restoration of the air space. In the fourth, not only has this desired aeration result failed to eventuate, but, in addition, the inflammatory process has permanently damaged certain of the structures forming the walls or approaches of the cavity by an infective tissue erosion. If the erosions are purely membranous, opposite the wider portion of the air space, they are usually followed by spontaneous cure and aeration of the cavity, but if in the region of the ossicles or tympanic ring, the attic, aditus, mastoid, or bony Eustachian tube they are prone to chronicity.

The size of the middle-ear cavity varies considerably in different individuals, even in adult life, and one that is abnormally small presents an anatomical factor of great moment in relation to the points just mentioned. Practically all the cases of chronic suppuration one meets with date from, or begin in, childhood, when this anatomical factor of size was most likely to operate. In contrast to this it is exceedingly rare to find such a condition in an adult in whom the first middle-ear inflammatory attack began indubitably when his growth was completed. I cannot recall one such case. From these remarks you will infer that factors unfavourable to the restoration of the middle-ear cavity as a functioning air space make for chronicity of disease.

Occasional discharge, occurring at intervals of months or more, implies an infection spreading along the middle-

ear tract from the nasopharynx and nose, associated with a cold in the head. It is a fresh invasion of an ear which supplicated previously, and is not due to any permanent local lesion. I have discussed this type already under watery discharges. If such a condition occurs in a child, the removal of adenoids gives a gratifying result, and if in an adult, the treatment of a pronounced nasal obstruction may be necessary, and equally successful.

Continuous discharge indicates a local lesion, and this may be situated in any portion of the middle ear, in the mastoid antrum, or Eustachian tube, and our hope of success in treatment will depend largely upon our ability to localize the exact site of the lesion. This is either an erosion of the soft tissue lining or of bone or even a necrosis of bone (invariably an ossicle), and the lesion is often covered more or less by granulation tissue, which is Nature's attempt at repair, and as a result of this process a discharge is produced. After cleaning out the ear, by syringing if necessary, and drying, a systematic examination on a definite plan will materially help.

Imagine the inner end of the meatus to represent the face of a watch. The tympanic membrane, if present, occupies this position, and when absent the inner wall of the middle-ear cavity does so. Divide this into anterior and posterior halves by a vertical imaginary line, from 12 to 6 o'clock, and into an upper and lower half by a horizontal line, from 9 to 3 o'clock. This will give four quadrants in any one of which or in more than one a lesion may be found. Note if the membrane is absent, or only a portion remains at the upper pole, or if it is nearly complete, but perforated, and what is the site of the latter. If adherent to, or well removed from, the inner wall by an air space.

Perforations and granulations in the posterior and upper quadrant are the most grave, as a cholesteatoma is fairly often present, causing some destruction of bone in the region of the external semicircular canal, with possibly severe attacks of vertigo. These cases must be treated by a radical mastoid operation without delay, as otherwise they may cause fatal complications. If the perforation is somewhere nearly central, well away from the periphery, and even if small, with a scanty, glairy, purulent discharge, filling the auditory meatus with 5 per cent. silver nitrate and then inserting an olive-shaped nozzle, to which is attached a piece of tubing and an air ball, to compress gently, but without much force, the fluid through the perforation, will often prove effective. I have seen cases of a year's duration dry up after one treatment. If some of the fluid passes through the Eustachian tube the prognosis is more favourable than if not, for the reasons I have mentioned above about air movements. If the perforation is at the periphery, either anteriorly or posteriorly, it is usually associated with caries of the tympanic ring. These are less promising in their response to treatment, and especially so if the air space is small and the membrane is adherent to the inner wall of the middle ear. If the membrane is absent a lesion of the bony tympanic ring can be easily seen, and treated with a good prospect of success.

Polypi and granulations, if large, may require general anaesthesia for their removal, but much can be done under the local application of Bonain's solution if the patient is fairly tolerant.

To enable silver nitrate to penetrate and be effective the epithelial covering of a polypus or granulation must be broken by pressure of a small curette or friction by a piece of wool. Making them bleed freely answers the purpose. Then apply 20 per cent. silver nitrate on wool repeatedly, by using a number of wool applicators on which the wool is rolled firmly, and after application are thrown away. If persisted in the bleeding will cease, and the area touched will turn white. If bleeding is very troublesome insert a few inches of ribbon gauze, soaked in the silver solution, and leave in for two days. Once a week is sufficiently often to do this, and on all other

days of the interim the patient has some iodized boric powder inserted. Formerly I have used ordinary boric powder, but now find the iodized preparation more effective:

In some cases with complete absence of drum, the middle-ear inner wall is seen to be granulating. These can be treated in the same manner. They may be more sensitive than around the tympanic ring, so 5 per cent. silver solution may be used instead of 20 per cent., and is usually quite strong enough, possibly because there is usually no caries here. If there is a mass of granulations in what appears to be the remains of the membrane in the upper part it usually includes a portion of the ossicles, which are possibly necrosed, and the removal of the entire mass by ossiculectomy or the radical mastoid operation will probably be necessary, but no harm comes from giving the silver treatment a good trial first. By this method we can get the more accessible areas to heal and follow extensions towards the attic or Eustachian tube. If there is still much evidence of disease in the attic, not easily reached by bent metal applicators, the radical operation will be necessary. With large loss of membrane this treatment is easily applied and effective, and when healed the middle-ear cavity is externalized, as it is with the radical operation.

A certain proportion of cases is seen where the middle ear is so small and ill developed, and filled so completely with granulating areas, as to compel the need for a radical mastoid operation to provide a cavity sufficiently large to give access for treatment. Considerable patience and perseverance on the part of the patient and surgeon are required, but the result often justifies it, as it is undoubtedly the only effective treatment I have found, short of the mastoid operation, and may in many cases dispense with the need of the latter. The following are my reasons for having adopted it.

For many years, in cases of extensive middle-ear disease, with granulations and suppuration, which had undergone long periods of treatment by syringing and the various antiseptic and astringent drops, I followed the usual practice of doing a radical mastoid operation. In a very large proportion of these I found only a sclerosed mastoid, with possibly a little septic debris in the antrum, but practically all the active disease present was encompassed by the boundaries of the middle ear, which could be reached through the external meatus. The opening of the mastoid and the removal of all the diseased middle-ear area at the operation did not ensure quick or certain healing of the newly made cavity with any form of dressing or even skin grafting, but, on the contrary, suppuration continued in a large percentage, which vitiated the desired and hoped-for surgical success. I then resorted to the silver treatment of the new cavity with great advantage, and subsequently came to the conclusion that, as so little was found in the mastoid itself in most of these cases, treatment of the middle ear in all that were suitable should be given a good trial first before undertaking any larger surgical procedure, and in consequence I have done fewer radical mastoid operations in recent years.

At least no harm and much good may come of trying this method, and certainly in all the cases which have responded well the hearing was vastly better than one usually finds after the radical operation.

FOREIGN BODY IN THE EAR

This occurs most often in children. Adults sometimes have pieces of wool in the ears, inserted to ease a slight ache, perhaps in cold weather, and forget about them. Examine first to see if a foreign body is present to ascertain its nature. If metallic or mineral it is usually hard, and if vegetable, soft. Syringing with watery solutions may remove the former if the stream is carefully directed between the meatus and the object; but if against the latter damage to the drum will result.

Watery solutions will cause vegetable matter to swell and probably necessitate the turning forward of the pinna, to expose the meatal tube deep to the foreign body, for its removal. Oil will not cause it to swell, therefore a good general rule is to drop in nightly for a week some warmed olive oil, and then syringe with bicarbonate of soda solution. A thin malleable wire loop can be inserted over the object to extract it, where forceps and probes cannot.

HAEMORRHAGIC DISCHARGES

Number three in the above classification has been considered already. Whenever blood or blood-stained discharge is found in an ear following an injury there is one golden rule to observe in treatment, and it is "never syringe." In the late war it was frequently done in cases of ruptured membranes following gunfire and shell explosion injuries, with the inevitable result of middle-ear suppuration.

The escape of blood and serum flushes the damaged breach, and if the external meatus is then made as aseptic as possible the lesion may heal promptly. Wipe out the meatus with sterile wool and 40 per cent. spirit. The pinna and outer part of the meatus may be painted with iodine or a picric acid solution similar to that applied to the skin prior to operations and covered with a sterile dressing. Haemorrhagic discharge of an influenzal middle-ear inflammation may, in the first instance, be treated in the same manner and then have 2 or 3 per cent. glycerin, acid. carbolic, dropped in twice daily. If there is much pain 5 or even 10 per cent. may be used.

The question of when or not to incise the inflamed drum membrane is a vexed one, on which otologists differ somewhat in practice. I have stated my opinion at some length in a paper read at the B.M.A. Meeting held at Eastbourne in 1931 and in some subsequent correspondence, and still hold to the same views. They are briefly these. I object to incising an inflamed membrane when there is no evidence of tension on it by secretion in the middle ear, as I hold that the infliction of a trauma on any inflamed tissue will most certainly lower its resistance to infection and diminish the maximum effort of its physiological reaction. Many such cases resolve without suppuration or certainly without external suppuration; with perforation, and if incised, both of the latter must obtain.

When, however, the cavity is filling with secretion and there is possibly no escape by the Eustachian tube, the membrane will then bulge outwards, and this is seen to take place invariably opposite the deepest part of the space, posteriorly to the handle of the malleus: release of the tension now is a sound surgical practice for three reasons:

1. Considerable tissue immunity to infection is present already at this stage, when inflammatory exudates are being poured out, and the drum will bear a trauma with greater impunity.

2. Release of tension now favours the subsidence of the inflammatory engorgement, which is a beneficial indication as disclosed by Nature's method of pouring out exudates at this stage.

3. Favours the exit of pus and entrance of air, with the consequent restoration of the air-space character of the middle-ear cavity.

The incision is usually made posteriorly, because the bulging of the membrane is seen here and as it is also the deepest part of the air space, though some factor other than bulging must be concerned with spontaneous rupture, or else all perforation should occur at this situation, which is not the case. The subsequent treatment may follow the lines already mentioned under acute middle-ear suppuration.

EPITHELIOMA OF EXTERNAL MEATUS

A very busy otologist may not see more than five cases of this condition in his own hospital and private practice in twenty years, so this will indicate its rarity when compared with other ear affections. Biopsy is the only sure method of establishing its nature. If seen early, before the lesion has spread widely, I have found radium followed subsequently by intensive x-ray treatment very satisfactory. Eight to ten radium needles, of 0.6 mg. strength, are inserted from without inwards around the circumference of the meatus, deep to the lesion, and left *in situ* for ten days. This is followed up by x rays for some months. Scarring and occlusion of the meatus is a frequent sequel, and, to prevent this, its patency should be maintained from the outset of treatment by a gauze packing or the insertion of a rubber tube.

CERUMINOUS DISCHARGE

If the mass is hard its removal presents difficulties, and attempts to dislodge it by forceful syringing may damage the drum. As the matter is rarely urgent I advise the use of warm olive oil nightly for a week, and the removal of the mass then is merely a question of syringing with a little technical skill. The nozzle of the syringe should never more than half fill the opened-out meatus, when the ear is pulled upwards and backwards to bring the cartilaginous portion of the passage into straighter line with the deeper bony portion. This enables the operator to direct the stream of fluid from the junction of the posterior and upper meatal walls towards the drum, and provides for its exit along the floor of the passage. A large nozzle will not prevent this; it will fill the outer opening and the stream is directed against the mass, and damage to the drum will result, with considerable pain to the patient. To facilitate the easier entrance of the fluid posteriorly to the mass, a small gutter can be made in the latter with a probe or small forceps, under illumination, through a speculum before syringing. A little refinement to the technique makes all the difference to the comfort of the patient, and, small as this minor operation may seem, it is not uncommon to find those who can recall with much regret some previous unpleasant experience.

If there is a history of middle-ear suppuration many years before, the existence of a perforation may now be assumed, and in such a case I prefer to try and remove the mass instrumentally rather than by syringing, as a fairly common sequence of the latter is reinfection of the middle ear followed by fresh suppuration, a development which will not bring credit to the attendant. Bicarbonate of soda, 2 drachms to the pint of water, at blood heat, is an excellent solution to syringe with. I frequently use soapy water, and think its physical properties aid in the expulsion of the mass.

The fourth International Congress of Radiology will be held at Zürich under the presidency of Professor Hans R. Schinz, from July 24th to 31st, when the following subjects among others will be discussed: radiodiagnosis of bone tumours, radiological appearance of the development of pulmonary tuberculosis, radiotherapy of cancers of the mouth and pharynx, short wave-lengths in treatment, and hard gamma rays and cosmic rays. Particulars may be had from the general secretary, Dr. H. E. Walther, 14, Gloriastrasse, Zürich. In connexion with the congress a special exhibition will be held comprising books, journals, etc., connected with radiology and associated sciences. The official opening of the congress will be on July 25th, by the President of the Swiss Confederation, at which meeting Professor Forsell will report on the organization of cancer campaigns.

X-RAY TREATMENT OF EXOPHTHALMIC GOITRE

BY

CHARLES S. D. DON, M.D. ABERD., M.R.C.P. LOND.
HONORARY PHYSICIAN TO SALFORD ROYAL HOSPITAL AND TO THE
ROYAL EYE HOSPITAL, MANCHESTER

The comparative scarcity of papers in our own medical journals on the x-ray treatment of exophthalmic goitre might be interpreted as indicating that there is little interest in this subject. In other countries numerous papers continue to appear. In January, 1933, Romanis stated in a paper in the *Journal* that "the results of x-ray treatment are not very impressive," and if one can judge by the correspondence which followed there is still interest shown in this line of treatment, and contrary views are held as to its merits. Douglas Webster,¹ Murray,² Cooper,² Connell,⁴ Rowden,⁵ Riddell,⁶ all wrote upholding x-ray therapy, while Joll⁷ gave the case against it. Douglas Webster wrote as follows: "In 1926⁸ I reported marked improvement in 82 per cent. of 107 cases; further experience, with nearly 200 cases in all, has confirmed this conclusion." Rowden⁵ stated that since 1905 he had treated several hundred cases with results at least as good as those claimed by surgery. Murray² gave strong support to x-ray therapy when he said that he had found surgical treatment to be advisable in about one-twelfth of the cases. In 1929⁹ I gave details of the cases I had observed, but, rightly or wrongly, I considered as failures all cases which had to have surgical treatment after having had any x-ray treatment. Barclay and Fellowes¹⁰ obtained good results in 90 per cent. of 300 private cases, while F. Hernaman-Johnson¹¹ obtained good improvement in 50 per cent. of all cases of Graves's disease.

As a physician one does not approach the treatment of patients with any bias towards either surgery or x-ray therapy, but with the aim of obtaining satisfactory results in a high percentage of cases. In assessing the results I have placed most reliance on the variations in the weight and the basal metabolic rate, on the pulse rate, the patients' symptoms and signs, and on their own opinions as to the value of the treatment. An increase in weight and a fall in the basal metabolic and pulse rates usually go hand in hand, but one finds cases where the improvement in general health and in the pulse and metabolic rates has been accompanied by very little increase in weight; on the other hand, an increase in weight does not always mean a big drop in the metabolic rate or pulse rate. By taking all these points into consideration, and by observing alterations in the tremor, the goitre, and the exophthalmos, when present, it is possible to give a very accurate opinion on the value of the treatment. It is quite possible for a patient to improve without iodine, or x-ray treatment, or operation, but as most of my cases had some definite form of treatment, I am unable to give a competent opinion on the frequency of such a spontaneous improvement. My experience with sodium fluoride is too small to permit comparison.

SCOPE OF PRESENT INVESTIGATION

The cases discussed are nearly all those which have had x-ray therapy at Salford Royal Hospital, and have been under observation for a minimum period of one year. In many cases the period of treatment and observation has been longer, but several are also included which were sent from x-ray therapy for an operation.

I am indebted to our radiologists, Dr. Higgins and Dr. Morris, for the following note on the x-ray technique.

Two areas were treated, using a tube current of 3 milliamperes, 6½ inch spark-gap (point to plate), through 3 mm. aluminium for five minutes, this being equal to a half Sabouraud pastille dose with the outfit used. This dosage was given at first twice a week, then once a week, and thereafter with increasing intervals between treatments as the patient improved.

The basal metabolic rate, the weight, and the pulse were taken in hospital as each patient was admitted from time to time into the ward for these examinations. Accurate estimation of the metabolic rate is difficult, and so I abandoned my attempt to carry it out on the patients without admitting them to the ward, as the results were too variable. Rest and a nourishing diet were insisted upon, but I did not prescribe iodine to any, and, so far as I know, very few of these patients had iodine from their private practitioner. It is probable that iodine has a limited sphere in Graves's disease, and I have found very little advantage from its continued administration. It is for this reason that, apart from times of emergency, iodine is only given to patients in order to prepare them for a thyroidectomy, as its value as a pre-operative treatment is most striking in those patients who have not received it previously.

In order to arrive at some estimate of the results of x-ray treatment I have divided the cases into "cure," "improvement," and "failure." I intend to consider 103 cases, and I find that during the first three months which elapsed from the onset of treatment ten patients had their treatment stopped and were sent to a surgeon for an operation to be performed. I do not propose to consider these ten cases further, as the treatment was stopped by the physician and not by the radiologist, and I do not think it is fair to include under "failure" cases which have had so little treatment.

Of the remaining ninety-three cases, at the end of six months' treatment seven had been operated on, and at the end of a year six more had been sent for operation. At the end of two years seven further patients had had operations, while at the end of three years one more case had found its way to the surgeon. In assessing the results I have included all these cases, but instead of classing them as x-ray failures, as I did in my previous paper,⁹ I have classified them according to whether there had or had not been any improvement at the time they ceased to attend the x-ray department. Some of these, therefore, are included under "improvement," and some under "failure"; none can be called "cured," as such cases would not have been sent to a surgeon. My reason for this classification of these operative cases is again because the radiologist did not in most cases recommend that x-ray treatment be stopped, and it is not beyond the bounds of possibility that further treatment might have resulted in improvement. The radiologist in some cases did advise that x-ray therapy should be stopped and another form of treatment tried. Such co-operation is of great help to the physician in charge of the case.

RESULTS OBTAINED

My records show that at the end of six months eleven cases could be considered cured, but as six months is too soon to consider all the cases these are merely mentioned as indicating that in some instances one can even hope for cure within that time. At the end of a year the results were as follows: cure, 29; improvement, 34; failure, 30.

I propose now to pass on to the final results, and it must be borne in mind that while some patients have been under treatment or observation from one to five years, some are included, as mentioned previously, who were operated on after having had x-ray treatment for a shorter period. The final results are: cure, 38;

improvement, 30; failure, 25. Of the seven cases which were operated on at six months four are included under "failure" and three under "improvement." Of the six operated on at the end of a year five are classed as "failure" and one as "improvement." If these thirteen cases are removed from the list the final results are changed, and become: cure, 38; improvement, 26; failure, 16.

In terms of percentages we then have the "cure" and "improvement" constituting 80 per cent. of the total. It is obvious, therefore, that the results could be made to appear excellent by simply excluding, on the grounds that they had not completed their treatment, all cases which were referred for surgical measures. On the other hand, by including all cases sent for an operation, the results seem quite mediocre, and in compiling the final results I have tried to steer a middle course. It would be of interest if writers were always in a position to state the number of patients who, within a reasonable time of their x-ray treatment, sought surgical treatment. It is possible that many whom a writer regarded as improved might not continue to feel the same enthusiasm about their improvement, and have tried other methods of treatment. Such a follow-up might show that a number had had operations, and the total would depend largely on the opinion which the physician in charge of the case had formed of thyroidectomy, and on the local mortality rate for that operation. My own figures, obtained on cases which were all sufficiently severe to require hospital treatment, suggest that unless approximately three out of ten such patients have an operation performed there will be many who, in spite of x-ray therapy, will suffer from chronic ill-health.

It will be observed that the final assessment shows a higher number of combined cured and improved cases than the figures given for one year's treatment, and it seems likely that the extension of the treatment beyond one year when necessary is justified, as some cases do not reach their maximum improvement at the end of one year. In following up cases year after year one finds, unfortunately, that recurrences or relapses may occur: my own records show that among the cases under consideration there were eleven patients who had recurrences or relapses, but that most of them improved with further x-ray treatment. One patient developed myxoedema and has to take thyroid regularly. The symptoms and signs came on just after treatment had been stopped, and when she consulted me six months later she was a well-marked case. Four patients died during treatment—one of pneumonia, one of mitral stenosis and heart failure, and two of Graves's disease.

I have discussed surgical measures in previous publications,¹² but I must refer to this again, as the thyroidectomy mortality rate is one requiring consideration when deciding on the line of treatment to be adopted. The mortality rate of all experienced surgeons is very low, and at Salford Royal Hospital it has been extremely low during the periods that the x-ray cases discussed in this paper were being observed.

Out of 155 cases operated on for toxic goitre there were only two deaths, both, I am told, from pulmonary embolism. These cases were operated on chiefly by Mr. Garnett Wright and by Mr. Jefferson, and they illustrate the low mortality rate which may be obtained by skilled surgeons. No fewer than forty-six of these cases had had x-ray treatment previously, and, whereas I have no details of the treatment given in fifteen of these, in thirty-one it was given at this hospital. In ten of these the treatment was given for less than three months, and was therefore incomplete. I mention this because surgeons sometimes make the unqualified statement that many of their cases have received x-ray therapy without improvement, and do not give details

of the treatment. The low mortality rate and the high percentage of cure attending surgical operations on the thyroid has made surgical treatment popular. Yet, although good surgical technique is the chief reason for the low mortality rate among our cases, it may also be due partly to the previous improvement in some severe cases under x-ray therapy, and partly to the fact that most of the patients on whom thyroidectomy was performed gave an excellent response to iodine when administered pre-operatively. Many of our cases were operated on from the medical side of the hospital and returned to it from the theatre. It is possible that some who were sent for operation might eventually have improved considerably had x-ray therapy been continued, but many of them might in the end have presented a serious surgical risk to life. Our x-ray cases were drawn from the working classes, and therefore it is the aim to try and produce satisfactory results in one year; this wish, coupled with our low surgical mortality rate, no doubt accounts for the fact that a greater number were operated on than Dr. Murray found necessary in his cases.

None the less, I believe that by sending cases which are not showing progress at an early date for operation a hospital as a whole is able to show a better percentage of improvement in all cases attending, and a lower surgical mortality rate. X-ray therapy should be given a trial in the large majority of cases, the results considered at three-monthly intervals, and those cases which do not show adequate improvement should be sent for surgical treatment. In the case of patients who, for financial or other reasons, cannot face more than a short absence from active life, an operation seems to be the treatment of choice.

TREATMENT OF ACUTE GONORRHOEA BY MEANS OF A NEW GONOCOCCAL VACCINE OF LOW TOXICITY

BY

I. N. ORPWOOD PRICE

PATHOLOGIST, THE LONDON COUNTY COUNCIL (WHITECHAPEL) CLINIC

AND

AMBROSE J. KING

CHIEF ASSISTANT MEDICAL OFFICER, THE LONDON COUNTY COUNCIL
(WHITECHAPEL) CLINIC

The treatment of gonorrhoea is generally acknowledged to be unsatisfactory, and the multiplicity of therapeutic methods which have been used may be regarded as an indication of their inefficiency. Unfortunately, we still lack a specific antidote. The local application of anti-septics has only a limited effect because certain areas of infection are frequently inaccessible. Drugs, whether given by mouth or by injection, are of uncertain value. Specific antisera, which raised such high hopes, have failed to fulfil their promise.

The various types of vaccine which have been used and recommended for years do not appear to have maintained a high standard of effectiveness. Despite many attempts to use vaccines in the acute stages of the disease, the effects have often been disconcerting, and accompanied by a high proportion of complications. Hence their use is generally restricted to chronic cases; but here again, owing to lack of antigenic power, results have often been indifferent.

Nevertheless, it was felt that if a vaccine of low toxicity could be prepared which, when administered to patients with acute gonorrhoea, would evoke a rapid and substantial antibody response, it should at least prove useful in the treatment of the disease. Such a vaccine has been prepared by one of us (I. N. O. P.), and this paper has been written to show:

1. The low toxicity of this vaccine.
2. The rapid and substantial response of the antibody-forming mechanism of the body (as measured by the complement-fixation test for gonorrhoea) following the administration of this vaccine.

The presence in the blood of specific as a result of this vaccine administration in: (a) curtailing the duration of the infection; (b) the prevention of complications; (c) curing the disease.

SUMMARY OF PREVIOUS WORK

It is stated by Thomson¹ that the first investigations of vaccine therapy in the treatment of gonorrhoea were made in 1907, when Wollstein, following the researches of Flexner on the meningococcus, showed that injections into animals of dead gonococci produced specific agglutinins and complement-deviating substances. In the same year Cole and Meakins² reported encouraging results in cases of gonococcal arthritis from the subcutaneous injections of large doses of gonococcal vaccine. Since these initial observations the subject has accumulated an enormous literature. Numerous observers have assessed results on widely different standards of cure, and a great variety of conclusions have been reached concerning the best method of preparation of the vaccine, the dosage, the type of case most suitable, and the stage of the infection at which the best results may be obtained. Autogenous vaccines and stock vaccines, recent strains and old subcultured strains, polyvalent strains and single strains—all have been recommended with varying results. These earlier workers relied mainly upon emulsions of killed gonococci injected subcutaneously or intramuscularly. Most of the vaccines so prepared were found to have the great disadvantage of marked toxicity. The general and local reactions which followed a dosage that was considered adequate were found to be distressing, and in weakly patients sometimes dangerous.

In 1913 Cruveilhier,³ following the researches of Bestedka (1911), prepared a gonococcal vaccine which was "sensitized" by the addition of serum from goats that had been immunized previously by the intravenous injection of dead gonococci. He reported good results in complicated cases and the absence of any severe general reaction following the use of this vaccine; but a slight rise of temperature with some transitory pain and redness of skin round the injection site sometimes occurred. He also recorded some good results with sensitized vaccines made from living gonococci. In the same year Broughton-Alcock,⁴ working with a vaccine similarly prepared, confirmed Cruveilhier's observations as to the therapeutic benefit derived from its administration in cases where complications had occurred. In a further series of cases (twenty-six) of acute gonococcal urethritis without complications he was not convinced of any curative effect.

Subsequently, numerous workers have concentrated upon the attempt to produce a non-toxic vaccine, and brief mention of the more important of these may be made. In 1913 Nicolle and Blaizot⁵ produced "Dmagon," a vaccine which was claimed to have been rendered non-toxic by culturing gonococci on a special medium and by their subsequent treatment with a solution of sodium fluoride. They then added to the vaccine a proportion of "syncocci"—Gram-negative cocci, which these authors believed to be frequently associated with the gonococcus. In 1913 Hirschfelder⁶ used an extract of gonococci. This was obtained by dissolving them in pan-

creatine and sodium bicarbonate solutions, and then acidulating with weak hydrochloric acid. Large doses of this solution were injected intravenously, but pyrexial reactions with malaise were apt to occur. Thomson (1919,⁷ 1920,⁸ 1922⁹) stated that he was convinced that the disappointing results from vaccine treatment were due to inadequate dosage—the dosage being, of course, restricted by the marked toxicity of vaccines in general use. By patient research he elaborated a complicated chemical method of removing the "endotoxins" from gonococci. After detoxication by his method initial subcutaneous injections of 5,000 millions to 10,000 millions of organisms could be given without ill effects, and the dosage by this route could be increased at short intervals up to a very large amount. Also, after a small preliminary sensitizing dose, large doses of this vaccine were given intravenously, again without unpleasant reactions. This preparation is still used and rightly esteemed, but the results obtained from it are admitted to have fallen short of early expectations. More favourable results are obtained from its employment in the treatment of chronic and complicated cases than in acute urethritis.

Lambkin and Dimond (1927¹⁰ and 1928) supplemented the routine treatment of gonorrhoea by intradermal and intramuscular injections, together with the intraurethral instillation of an "exotoxin" derived from cultures of gonococci grown on a medium containing animal nucleo-protein. Briefly, they observed that gonococci grown in cultures of this kind produced "polar bodies" histologically similar to those associated with the diphtheria bacillus. They washed off gonococci plus their polar bodies from the culture with 2 per cent. saline solution, and allowed the wash to stand for three or four days. This was found to separate into three distinct layers. The bottom layer contained heavy gonococci; the intermediate layer was a lighter white, powdery material termed "alpha nucleo-protein"; and the supernatant clear fluid contained a substance termed "beta nucleo-histone." The two upper layers were believed to result from the splitting by the saline solution of the polar bodies into their main constituents. The beta nucleo-histone, which was separated in this way from the poisonous endotoxins resulting from autolysis of the gonococci, was employed as the vaccine. This was found to have marked antigenic properties, and could be tolerated in doses which were large when compared with the equivalent in ordinary vaccine. The method of preparation is, however, a complicated one, and accurate standardization is difficult. Some excellent results have, nevertheless, been reported, and investigation is still proceeding along these lines. Clements and Oliver,¹¹ using a modification of this preparation, have recently reported some good results in chronic cases.

THE VACCINE DESCRIBED

Many attempts have been made to utilize the various vaccines described above during the acute stage of gonorrhoea, but the results have generally been unsatisfactory and accompanied by a high proportion of complications, which seem to "flare up" suddenly after the administration of the vaccine. Consequently, gonococcal vaccine therapy is not generally favoured for acute gonorrhoeal cases. The ideal vaccine is one which combines ease of preparation and powerful antigenic qualities with the absence of marked toxic effects following its administration.

The vaccine described below is not claimed to be ideal, but it would appear to combine these cardinal merits to a greater extent than any vaccine with which we are acquainted.

Technique of Preparation

Gonococci, grown on hydrocele agar (pH 7.5) in a triangular Roux bottle at 37.5° C. for forty-eight hours, were washed off into a cylinder with 100 c.cm. of physiological saline; this yielded a suspension of about 180 millions of organisms per c.cm.; 1 c.cm. of N/1 NaOH was added, and the cylinder placed in the 37.5° C. water-bath for two hours, when most of the organisms were found to be in solution. The fluid was filtered through sterile lint, 1.5 c.cm. of N/1 HCl added, and the cylinder returned to the bath. After fifteen to twenty minutes white flocculi appeared, and these were centri-

fuged out of solution (3,000 revolutions per minute) and then suspended in 9 c.cm. of sterile saline. N/1 NaOH was added to the suspension drop by drop until a pH of 7.5 was reached, when the precipitate appeared to go into solution. To this 1 c.cm. of formo-saline (1 per cent.) was added. This colloidal suspension of gonococcal protein constituted the vaccine, 1 c.cm. of which contained the protein content of approximately 1,800 million gonococci.

CLINICAL APPLICATION

This preparation was employed in the treatment of forty-six men who were suffering from acute gonococcal urethritis. The occupations of the men are of interest, and may be analysed as follows: twenty-four manual workers, eighteen sedentary workers, and four unemployed. Their ages varied from 19 to 42 years, the average being 26½ years. The incubation period varied from one day to twenty-four days, but in the majority of cases evidence of infection was present within a week. When first examined at the L.C.C. (Whitechapel) Clinic the infection was apparently limited to the anterior urethra in thirty (65 per cent.) of these patients, but the remaining sixteen (35 per cent.) were suffering from both an anterior and a posterior urethritis. In most cases the patient presented himself for treatment, and the first dose of vaccine was administered within six days of the onset of the symptoms.

Dosage and Method of Administration

As already stated, the vaccine was made up so that 1 c.cm. was equivalent to the protein content of 1,800 million gonococci. All injections were given subcutaneously over the gluteal muscles, the right and left sides being injected alternately. The initial dose in each case was 1/4 c.cm. (450 million organisms), and this was increased to a maximum dose of 1.5 c.cm. if no untoward manifestations occurred. The actual amounts of vaccine received by the patient are shown in the table below.

Number of Patients	Consecutive Days									Total Amount of Vaccine Received per Patient
	1	2	3	4	5	6	7	8	9	
5	½	½								1 c.cm.
3	½	½	½							2 "
10	½	½	½	½						1 "
9	½	½	½	½	½					2½ "
3	½	½	½	½	½	½				1½ "
5	½	½	½	½	½	½		½		2½ "
1	½	½	½	½	½	½		½	½	2 "
2	½	½								2 c.cm.
2	½	½	½	½						1½ "
1	½	½	½							1½ "
2	½	½	½	½						2½ "
1	½	½	½	½	½					2½ "
1	½	½	½	½	½	½				2½ "
1	½	½	½	½	½	½		½		5½ "

This shows that the period during which vaccine was administered varied from two to nine days, whilst the total amount injected in any one case ranged from 0.5 c.cm. (the protein equivalent from 900 million gonococci) to 5.25 c.cm. (the protein equivalent from 9,450 million gonococci). Two groups of patients are represented in the table. Group 1 represents the earlier patients, none of whom received more than 0.25 c.cm. per diem. With the experience gained from the reactions of the patients in this group we were able, in most of our later cases,

to advance the dosage more rapidly. This is shown in Group 2. The injections were given each day where possible, but the daily and the total dosage were modified according to the individual reaction.

Immediate Results

A local reaction occurred in every case. The mildest reaction consisted of a tender, slightly indurated, circumscribed area of approximately $1\frac{1}{2}$ inches in diameter at the site of injection, with a slight enlargement of the nearest inguinal glands. This was accompanied by mild subjective discomfort. A good reaction was indicated by a painful indurated area 5 inches in diameter, with enlarged painful inguinal glands. In such cases as these the site of injection was covered by an area of vivid scarlet erythema, from which a well-marked red band of lymphangitis extended across the buttock and round the flank to the inguinal glands on the same side. The skin overlying the glands became red and tender. The acute local signs and symptoms following injection produced their maximum effect within twenty-four hours of the administration of the vaccine and took two to three days to subside, while the subcutaneous induration remained for a day or two longer. The local reaction in twenty of the forty-six patients injected was moderate, and confined to the immediate site of the injection. In twenty-six patients, in addition to the tenderness and enlargement of the corresponding inguinal glands, a well-marked induration developed at the point where the vaccine was injected. In seven of these a well-marked band of lymphangitis was present. This tracked from the area of induration at the site of injection to the enlarged tender inguinal glands on the same side.

The general reaction consisted of symptoms which ranged from a slight headache and malaise to a severe rigor with vertigo, nausea, retching, and vomiting in some cases. Occasionally insomnia and restlessness were well marked, but in most cases the only result was a headache of moderate severity and some feverishness. These symptoms, which did not invariably follow the first injection, were alleviated by mild analgesics such as aspirin or pyramidon. A general reaction was absent in ten (21.7 per cent.) of the forty-six patients injected. In thirty-four (73.9 per cent.) some general reaction developed in from one to five hours after injection. In only two patients (4.4 per cent.) was the general reaction so severe that the vaccine treatment was stopped after the second dose had been administered.

CLINICAL RESULTS

The clinical results following injection of the vaccine may be classified into two groups:

Group 1.—Those in which the signs and symptoms of the infection remained absent after a definite period of time. These may be subdivided as follows:

(a) Absence of signs and symptoms within ten days from beginning of treatment. In five (10.8 per cent.) cases the absence of urethral discharge or other symptoms, and the absence of haziness and threads from both specimens of urine, were noted after ten days' treatment or less. One of these cases, which will be mentioned later as the most rapid cure in the series, remained entirely without symptoms or signs after only three days' treatment.

(b) Absence of signs and symptoms within two to four weeks from beginning of treatment. These consisted of nineteen cases (41.3 per cent.).

(c) Absence of signs and symptoms within one to three months from beginning of treatment. This group contained sixteen cases (34.8 per cent.); in a proportion of these patients this clinical improvement occurred in

spite of irregular attendance and neglect of routine treatment.

In this whole group of forty (86.9 per cent.) cases the results may be said to be satisfactory.

Group 2.—Those cases which developed acute complications of gonorrhoea. There were only six cases (13.1 per cent.) in this group. Two of them developed a unilateral acute epididymo-orchitis; two had periurethral abscess of the penile type; one suffered from an acute prostatitis and vesiculitis, which was accompanied by gonorrhoeal rheumatism. The sixth case was transferred to another department as a suspected case of chronic pyelitis. No complications occurred during the period of vaccine administration. The shortest time between the cessation of the injections and the onset of a complication was two days.

The above results may be compared with those obtained by ordinary routine treatment. In order to do this the records of 100 unselected patients, who originally attended this clinic suffering from acute gonorrhoea, were examined, and the proportion of these cases which developed acute complications of the disease during their early treatment was noted. Of the 100 unselected patients, twenty-four developed acute complications, an analysis of which is shown below.

Acute epididymo-orchitis	12 per cent.
Acute prostatitis	5 " "
Periurethral abscesses	4 " "
Acute arthritis	1 " "
Gonorrhoeal rheumatism	1 " "
Gonorrhoeal teno-synovitis	1 " "
				24 " "

SEROLOGICAL RESULTS

These may be divided into three groups:

Group A.—Those in which the complement-fixation test for gonorrhoea (Price's former technique¹²) was negative in the blood serum at the onset of treatment, but became positive within ten days. This group contained thirty-four (73.9 per cent.) cases, and the results are tabulated below.

G.F.T. at Onset of Treatment	G.F.T. within Ten Days or Less	Number of Cases
Negative	++ (40) strongest positive	1
"	++ (20) very strongly positive	2
"	++ (5 to 10) strongly positive	14
"	+ positive	12
"	± weakly positive	5
	Total ...	34

The bracketed figures show dilutions of the serum—for example, (40) indicates that the serum was diluted 1 in 40. It should be remembered that without treatment a positive gonorrhoeal complement-fixation test, as recorded by the above technique, is not usually obtained in acute cases until fourteen to twenty-one days after the onset of symptoms. These cases, however, had been treated by routine methods (irrigations, etc.), and therefore positive serum reactions were not to be expected until later in the course of the disease.

Group B.—Those in which the complement-fixation test was positive at the beginning of treatment, but showed a definite increase in the strength of the reaction at the end of the period of vaccine administration. This group included four (8.7 per cent.) patients whose sera behaved as shown:

Patient	Complement-fixation Test	
	First Day	Tenth Day
First	±	++ (20)
Second	+±	++ (40)
Third	+±	++ (40)
Fourth	±	++

Group C.—Those in which the complement-fixation test was negative at the outset, and in spite of vaccine treatment remained negative at the end of ten days. This group consisted of seven (15.2 per cent.) cases. Later in the course of the disease a weakly positive (±) reaction developed in three of these cases, but evidently this was not due to the effect of the vaccine. The remaining four failed to record a positive reaction at any time. Five of these seven cases were the least satisfactory of all the cases in the series from the point of view of clinical results. The two remaining patients showed a remarkable and unexpectedly rapid recovery; the reason is not apparent. One case, not included in this classification, was a patient who refused to allow more than one venepuncture, and subsequently defaulted.

END-RESULTS

In view of the widely divergent views held as to the standard of cure on which results of treatment should be assessed, the test of cure employed in all these cases is set out below.

1. **Urethral Discharge.**—Absent.
2. **Urine:** "Two-glass" Test.—Both specimens were free from haziness and threads on repeated examination.
3. **Rectal Examination.**—Clinical evidence of infection of the prostate or seminal vesicles was absent on digital examination.
4. **Microscopical Tests.**—Three successive smears of the contents of the prostate and the seminal vesicles taken at intervals of one week or more showed less than five leucocytes per 1/12 microscopic field.
5. **Instrumental Examination.**—(a) A metal sound of average size (16/20 Clutton) was passed into the bladder without difficulty. (b) *Urethroscope:* No lesion could be detected in the anterior urethra.
6. **Complement-fixation Test for Gonorrhoea.**—This had to be completely negative. The complement-fixation test employed as a test for cure in all but one case in the series was Price's improved method.¹² This more sensitive technique considerably enhances the value of the test as a criterion of cure.
7. **Provocative Diet.**—A negative complement-fixation test for gonorrhoea and no excess of leucocytes in the prostatic and vesicular smears after a provocative diet, including alcohol and spices, for a period of from two to four weeks.

At this stage it would be well to emphasize the importance of the complement-fixation reaction for gonorrhoea in the test for cure of patients, even in those who have undergone vaccine treatment. Many authorities believe that the results of the complement-fixation test for gonorrhoea are valueless when applied to the sera of patients who have received gonococcal vaccines. It was definitely established in the course of this investigation that the injection of vaccine stimulates the production of antibodies (as demonstrated by the complement-deviation test for gonorrhoea) only so long as the administration is continued. In cases in which we were able to establish a rapid cure the reaction became negative in approximately six weeks from the cessation of vaccine treatment. But it was also established that if the

complement-deviation test for gonorrhoea remained positive more than six weeks after the vaccine had ceased to be injected it was invariably possible to demonstrate a persistent focus of infection.

On reviewing the end-results of any treatment for gonorrhoea one is always confronted with the difficulty of patients who default when they become symptomless, although they may not necessarily be cured. In this category were fifteen (32.6 per cent.) in the series of forty-six patients who failed to pursue their treatment upon the cessation of symptoms. Of these, ten did not return, and so no assessment of the curative value of the vaccine treatment could be made in these cases; three defaulted whilst undergoing their final tests, so that a cure could not be established; two defaulted but returned later with symptoms.

The final tests of cure were passed by twenty of the remaining thirty-one patients. The varying periods of treatment before cure of these twenty patients are set out in the table below.

Number of Patients	Period of Treatment before Cure
1	7 days
3	6 weeks
1	8 "
2	12 "
1	16 "
2	18 "
2	20 "
3	28 "
1	32 "
2	36 "
2	40 "
20	

From this it will be seen that of the twenty patients who remained under observation throughout the clinical course of the disease and were cured seven were discharged within three months, eight within six months, and five within ten months.

The following table shows the results obtained in twenty unselected cases treated by routine methods, *without vaccine*, during the same period. The same standard of cure was, of course, adopted.

Number of Patients	Period of Treatment before Cure
1	8 weeks
3	12 "
6	20 "
4	24 "
3	28 "
2	32 "
1	40 "
20	

Comparison of the two tables shows that a somewhat larger proportion of rapid cures was obtained in the patients treated with the vaccine.

Apparently, cure of the disease was not hastened by vaccine in the remaining eleven patients. Two reached the test of cure stage after twelve and fifteen months respectively. Nine still remain under treatment after periods varying from ten to eighteen months. It must be remembered that these cases were all treated as out-patients, and most of them continued their daily work, so that adequate control of their actions and habits during this period was impossible.

CONCLUSIONS

1. This vaccine is a powerful and prompt stimulant to the production of gonococcal antibodies as demonstrated by the complement-fixation test for gonorrhoea. When employed in the acute stage of the disease in the manner already described—that is, daily injections—thirty-eight (82.6 per cent.) patients out of forty-six showed a marked increase in the strength of their serum

tests within ten days—namely, during that period of the disease when such a result is not to be anticipated.

2. In view of the protein equivalent of the number of gonococci (1,800 million per c.cm.) contained in this vaccine, it may well be described as a detoxicated vaccine. Furthermore, it can easily be prepared and standardized.

3. No fixed method of dosage of the vaccine is possible. The maximum dose which a patient will tolerate can only be found by the individual response of the patient to gradually increasing doses.

4. In those patients who responded serologically to the vaccine a definite clinical improvement almost invariably followed within a short time, but the percentage of cases which subsequently presented symptoms of chronic infection was not lessened.

5. Where serological response to the vaccine was not forthcoming the results were disappointing in all but two cases.

6. Two cases which showed no serological response made a rapid recovery. The explanation of this is not apparent.

7. No acute complications occurred as a result of the vaccine, although it was administered during the acute stage of the disease. The number of acute complications—six (13.1 per cent.)—occurring later in the course of the disease in patients treated by this method is definitely lower when compared with patients treated by ordinary routine methods alone (24 per cent.).

8. The time taken to effect a cure is somewhat shortened in some cases when the routine methods of treatment are supplemented by the administration of this vaccine, but on the whole the results are disappointing.

9. It would appear that the type of gonococcal infection most likely to be benefited by treatment with this vaccine is that in which the patient is suffering from a chronic gonococcal complication such as arthritis, and the blood, when tested by the complement-fixation reaction, reveals a low (\pm) specific gonococcal antibody content. This point is at present under investigation (A. J. K.). Of the forty-six cases treated with vaccine, thirty-eight showed an increase in the antibody content of the blood (as evidenced by the complement-fixation test), and a definite decrease in the severity of the clinical symptoms within ten days of the first vaccine injection. It would be natural to anticipate that the time taken to cure these patients would be definitely shorter than when the ordinary routine methods of treatment are employed. This, however, was not the case, and, whilst admitting the danger of drawing conclusions from such a small number of cases, it would appear that specific gonococcal antibodies tend to prevent the occurrence of severe acute complications and to shorten the acute stage of the disease, but seem to have little effect in eradicating the infection from its localized sites in the genital system. This would account for the disappointing results from the use of gonococcal vaccines, prepared in all manner of ways, in the routine treatment of gonorrhoea.

NOTES ON A SMALL OUTBREAK OF
GLANDULAR FEVER

BY

E. J. BRADLEY, M.D.CAMB., F.R.C.S.ED.

SURGEON, MARGATE AND DISTRICT HOSPITAL

Glandular fever in epidemic form is not an uncommon disease. The literature¹ on the subject has grown during the last few years; but some of the cases occurring in the outbreak now to be described showed certain unusual symptoms, which are the main reason for these notes.

The cases arose in a preparatory school in October, 1933. Out of eighty-four boys eleven developed the disease; two cases were of alarming severity, three others were severe in type, the remainder were moderate or mild in character. All boys in the school occupy separate bedrooms or cubicles, but it is of interest that a direct relationship could be traced among the infected boys in friendship, or proximity in work and play. Further, a case of chicken-pox arose early in October, and although there were over sixty vulnerable boys, no other contracted this disease, so that the methods of isolation and prophylaxis, valid in the latter disease, were of no avail in glandular fever. The cases occurred within the space of twelve days. The school was disbanded on the fifteenth day after the onset of the epidemic and reassembled on the thirty-second day. Of the boys sent home two only developed the disease, and those in mild and attenuated form. Six of the adults in attendance on the boys fell ill, five with frank follicular tonsillitis and one with a doubtful attack of glandular fever. Nine out of eleven boys had had their tonsils removed; the illness of the two who retained them was mild in type.

As the cause of the disease is unknown, search was made among the domestic staff for a possible carrier of throat infection, but without any definite result. Analysis of the milk and water supply proved negative, and the drainage system of the school, tested regularly, was beyond reproach. Sporadic cases of glandular fever had arisen in the district during the previous two months, which had been prolific in producing other throat infections, and notably scarlet fever.

SYMPTOMS AND SIGNS

Before describing any case in detail the following general statement of symptoms and physical signs is given.

Onset.—The first complaint, in the majority of cases, was of the collar being too tight. This was followed by pain or stiffness of the neck. Slight fever occurred in the beginning, and the groups of glands under the sternomastoid muscles or in the submaxillary triangles were found to be tender and enlarged. There was vomiting at onset in five cases; headache was not noted.

Development.—Fever increased quickly and the glands became more swollen. Usually both sides of the neck were affected, but not equally. Glands in the posterior triangles of the neck were quickly and commonly affected; the axillary and inguinal groups of glands enlarged definitely in only four cases. Peradenitis developed in the severe cases, the cervical swellings becoming diffuse and very tender. Dysphagia occurred as a sequel of this, produced in two cases by oedema of the palate and fauces. An enlarged spleen was noted twice, enlargement of the liver once. Epistaxis gave some relief to the congestive symptoms early in the disease. A rash was observed in two cases only, once urticarial and once macular in type. All severe cases showed a typical feature, which came to be regarded as almost diagnostic. When asked to sit up in bed a hand was placed behind

the back of the head and the head and trunk raised in one piece till supported on the other elbow. In mild cases the temperature settled on the third or fourth day. In others it proved very erratic, settling, then rising again. Spasms of pain in the throat occurred even in cases where the fauces were but little affected. Even in mild cases the boys became more ill than seemed warranted by their physical signs; and the severe cases were rapidly debilitated by the fever, pain, and anorexia. There was a definite tendency to relapse, and it was found wise to keep the boys in bed until ten days after the cessation of fever.

Pathology.—Examination of the blood in selected cases showed a mononuclear lymphocytosis, which developed after the third day, and was well marked at the end of the third week of illness. Throat swabs taken in certain of the cases were negative for haemolytic streptococci and Klebs-Loeffler bacilli. Where abscess formation occurred the organism cultured from the pus was a non-haemolytic streptococcus.

Complications.—The following arose in three separate instances: acute retropharyngeal abscess, suppuration of a cervical gland, and acute otitis media. No haematuria or nephritis occurred. The following sequelae were noted: tachycardia, anaemia, persistent glandular enlargement (six weeks or more), and slight, irregular temperature.

Differential Diagnosis.—During the first forty-eight hours there may be a resemblance to mumps of the submaxillary type. Follicular tonsillitis is distinguished by the throat appearance and the fact that the fauces are affected primarily and the glands next. The absence of a definite rash in glandular fever should be sufficient to distinguish it from scarlet fever. Tuberculous adenitis and lymphadenoma both have certain features in common with glandular fever, but time and a biopsy in persistent cases will prove deciding factors. A differential blood count in the acute stages, though not to be taken as diagnostic, may be regarded as confirmatory of glandular fever if a mononuclear lymphocytosis be present.

INDIVIDUAL CASE RECORDS

Case 1 (aged 11)

On October 6th this boy went to bed with an ordinary feverish cold, stayed in bed two days, then appeared well until October 15th, when he complained of stiff neck and pain just to the left of the larynx. His temperature was 99°F , and he was put to bed at once. Examination showed nothing in the throat and no enlarged glands. On October 15th the glands in the left substernomastoid region and in the posterior triangle on that side were enlarged and tender; there was some dysphagia, and the temperature was 100° . Next day the pain grew more severe, shooting up into the left ear, the glandular swelling was more diffuse, and the left side of the soft palate showed oedema. The glands on the right side of the neck began to swell, and the temperature rose to 102° .

On October 17th the fauces were more oedematous and very painful; there was constant clearing of the throat and hawking up of mucus. Nothing but fluid could be taken by the mouth, and the temperature in the evening rose to 104° . On October 18th there was expectoration of blood-stained mucus from the throat, the pain in the throat and neck was severe, the evening temperature was again 104° , and sleep was poor, with some delirium. Next day the oedema and swelling of the throat began to abate, epistaxis occurred, the temperature was falling, and there was some general improvement, though the day was disturbed by bouts of abdominal pain. By the evening of October 20th all the oedema had gone from the throat, the gland swellings were subsiding, and fluid nourishment was taken freely. On October 21st there was further subsidence of physical signs and symptoms, except for sudden and unaccountable spasms of pain in the throat.

On October 23rd the temperature began to rise again, and the left tonsillar region became swollen and angry. On October 24th the temperature rose to 104° , the left side of the pharynx was swollen, but not oedematous; the glands in the neck, however, remained less swollen and less painful. By October 26th the swelling of the fauces was receding and displayed another swelling on the posterior wall of the pharynx. Next day there was a definite localized retropharyngeal abscess, and this was incised "per os" and the pus evacuated. On October 28th the temperature, which

CHART I.—Case 1: (A) Oedema of palate and fauces; (B) Tonsillar swelling; (C) Retropharyngeal abscess incised; (D) Went home.

had dropped, rose again, reaching 104° , but the throat was comfortable, the glands less swollen, and the boy was beginning to eat and take interest again. From October 29th to November 1st the temperature was of the swinging, septic type, but subsequently subsided, except for occasional small irregularities. No further untoward symptoms arose, and convalescence, though slow, was uneventful.

Case 2 (aged 13)

On going to bed on October 15th he noticed that his collar felt too tight. Next morning the right side of his neck was stiff and painful; at 10 a.m. his temperature was 102° , and there was marked glandular swelling under the right sternomastoid muscle; the fauces then showed nothing abnormal. By noon the swelling had increased rapidly, spreading up under the jaw and to the ear. By 6 p.m. dysphagia was present and the right palate and fauces were oedematous; at 8 p.m. fluid swallowed was regurgitated through the nose, and there was slight laryngeal stridor. The temperature rose to 103° , and the glandular swelling was very tender and painful. At 3 a.m. on October 17th, after an attack of

CHART II.—Case 2: (A) Larynx; (B) Pain on neck.

coughing, stridor became more acute, but spraying of the throat with adrenaline seemed to relieve this; swallowing became more comfortable, and by 6 a.m. the temperature fell to 99° . Swelling of the glands on the left side of the neck appeared, but that on the right was definitely subsiding. The glands in both axillae were found enlarged. On October 18th there were brief repeated bouts of epistaxis, with considerable relief to the oedema and swelling, whilst the pain became easier. A differential white blood count showed no abnormality.

On October 19th the temperature was settling, the faucial oedema had gone (petechiae showed on the mucosa), and there remained a diffuse, hard swelling under the upper third of the right sternomastoid muscle. On October 20th the spleen was felt. On October 21st the temperature rose to 101° , the glands on the left side of the neck became more swollen and tender, and a general macular erythema appeared. On the 23rd earache started, the temperature rose to 103° , and the membrana tympani was found to be thickened, red, and pulsating. Next day the temperature was still high; paracentesis of the membrane was performed, with liberation of pus and relief of pain. This was followed by a gradual settlement of the temperature, and convalescence proceeded uneventfully, but for a persistently high pulse rate and occasional rises of temperature to $99-100^{\circ}$.

Case 3 (aged 13)

On October 8th this patient went to bed with a feverish cold. On October 11th his temperature rose to 102° and the right submaxillary gland was found to be swollen and tender. On October 13th he vomited and complained of dysphagia, and the glands in the posterior triangles of the neck were enlarged and tender. On October 16th the fauces were swollen, but not septic, the glands large and tender on both sides of the neck. Two days later he complained of headache and pain low down in the throat. On October 20th

CHART III: CASE 3.

he was more comfortable, but the glands were still tender and the temperature irregular. On October 23rd there was pain in the upper part of the chest and a sense of constriction, which was thought to be due to enlargement of the glands in the mediastinum; this subsided in forty-eight hours. The temperature settled, but for minor irregularities, and no further symptoms of note developed, apart from anaemia. A differential white blood count on October 30th gave the following: polymorphs, 48 per cent.; small mononuclears, 47 per cent.; large mononuclears, 5 per cent.

A fourth boy, who ran a very mild course for a fortnight, relapsed on the fourteenth day, and had a much more severe bout, with high fever, dysphagia, and glandular swelling lasting a further ten days.

Treatment.—This was necessarily empirical. Phenazone and quinine were tried without any obvious effect. Anti-phlogistine externally and throat sprays of hydrarg. perchlor. 1 in 1,000 and of adrenaline 1 in 1,000 seemed to give relief.

SUMMARY

Certain of the cases described showed a very acute onset, a marked degree of periaidenitis, and oedema of the palate and fauces, leading in one instance to laryngeal stridor. Unusual complications arose in the shape of an acute retropharyngeal abscess, and a cervical abscess (in a case not described in detail).

I am deeply grateful to Dr. F. J. Poynton for his advice on the outbreak in general, and to Dr. G. F. Still for his help and interest in one particular case.

ON THE DIAGNOSTIC SIGNIFICANCE OF A POSITIVE SPUTUM REPORT

(DIRECT EXAMINATION FOR TUBERCLE BACILLI)

BY

G. GREGORY KAYNE, M.D., M.R.C.P.

DOROTHY TEMPLE CROSS RESEARCH FELLOW IN TUBERCULOSIS

A great deal of attention has lately been focused on the neglect of the early diagnosis of pulmonary tuberculosis. It may not, therefore, be untimely to stress a certain aspect of the *wrong* diagnosis of pulmonary tuberculosis, which has not received the notice it deserves in view of the important social and economic consequences to the individual concerned.

The student is rightly taught that one or even several negative sputum examinations do not justify the rejection of a diagnosis of pulmonary tuberculosis; but neither he, the general practitioner, nor the tuberculosis officer has his attention sufficiently well drawn, either in textbooks or post-graduate lectures, to the fact that a single positive sputum report by no means always establishes the diagnosis. As clinical assistant to the tuberculosis dispensary at the Hospital for Consumption, Brompton, I saw several patients sent by their medical attendant with the diagnosis of pulmonary tuberculosis based on a single report of "T.B. found in the sputum," in whom subsequent physical examination, x-ray of the chest, repeated sputum examinations, and prolonged observation (including a stay in hospital) showed no evidence of active disease. The reports of the sputum examinations emanated from a pathological laboratory of high repute, and the patients had been promptly notified by their private practitioners.

It is unnecessary here to emphasize the significance of such a label to the patient. But the position of the tuberculosis officer also is not an enviable one. He must continue to keep the patient under observation for several months at least. If at the end of this period he is still convinced that the patient has no active pulmonary tuberculosis, he can hardly remove him from the dispensary register as "cured"! Two alternatives lie before him.

(a) He can himself denotify the patient as "notified in error," or as "diagnosis not confirmed." Such action requires some courage, for occasionally a patient will develop pulmonary tuberculosis shortly afterwards, purely as a coincidence, and the tuberculosis officer will undoubtedly be blamed as having mishandled the case.

Thus Rist¹ found that of 192 patients, representing a consecutive series of hospital nurses (see below), referred to him at the Dispensaire Léon Bourgeois of the Laennec Hospital as diagnosed or suspected cases of pulmonary tuberculosis, and discharged by him as non-tuberculous, after sufficiently detailed investigation to ensure that no error had occurred, two developed active pulmonary tuberculosis within six months and one year respectively.

(b) The tuberculosis officer can communicate with the patient's private practitioner, giving his findings and suggesting that the latter denotify the patient. This procedure will, however, prove awkward for the doctor, who will probably be accused by the patient of bungling, and will certainly be blamed for the great inconvenience caused by the notification.

Rist discussed this subject at some length in a recent post-graduate lecture in Paris. Since 1923 he has been chief medical referee for tuberculosis to all the nursing staff of the hospitals of the Assistance Publique. While the latter correspond to the municipal hospitals now under the L.C.C. they actually include nearly all the hospital beds available in Paris, as voluntary hospitals consist of only a few religious institutions. All staff diagnosed as, or suspected of, pulmonary

tuberculosis are referred to him at the Laennec Hospital by the general medical referees. In 1923 he published¹ the results of the first year's work of this department. Of ninety nurses referred to him as cases of pulmonary tuberculosis with a report of tubercle bacilli in the sputum the diagnosis was not confirmed in twelve (13.4 per cent.).

SOURCES OF ERROR

The reasons for the findings quoted in the preceding paragraphs may be grouped as follows:

1. *Errors of Technique.*—These have been fully dealt with by Wilson² in a recent report from the aspect of research work. In carrying out routine sputum examinations the following causes of error must be considered.

(a) Mistakes in labelling of specimen jars, slides, and reports.

(b) Using slides which have been previously employed for making smears containing bacilli.

(c) Drying smears with blotting paper previously used.

(d) Employing tap-water for diluting stains or washing the slides. (Tap-water frequently contains non-pathogenic acid-fast bacilli.³)

(e) Using contaminated cedar-wood oil and bottles of stains.

(f) Occasionally mistaking artefacts due to scratches on slides, or crystals of stain, for bacilli.

The possibility of some of these errors should particularly be kept in mind when only an occasional bacillus appears to be present.

2. *Dishonesty.*—The sale of bacilli-laden sputum unfortunately proved not un lucrative during the war, and one can postulate circumstances even in civil life when such means might be adopted. In the Assistance Publique of Paris a nurse automatically receives leave on full pay, for at least two years, immediately the diagnosis of pulmonary tuberculosis is made, and temptation may therefore sometimes prove too great. Further, the increasing number of pathological "services," some with inadequately trained staff, may be made use of by charlatans requiring some justification for the prolonged and costly treatment advised to the patient.

3. *Tuberculous Staff.*—A laboratory attendant suffering from open pulmonary tuberculosis may contaminate material in a laboratory for some time before his condition is detected.

4. *Other Acid-fast Organisms.*—Finally, attention must be drawn to recent papers which have described the occurrence in man of other acid-fast organisms. Branch⁴ reviews the question and describes the occurrence of non-mammalian tubercle bacilli (some of them belonging to the avirulent avian group) in the skin, pleural fluid, and blood cultures. Cummins and Williams⁵ describe an acid-fast bacillus ("M" bacillus) found in the sputum of a female patient suffering from severe pulmonary disease and achalasia of the cardia; they were unable to decide whether it was an adventitious saprophyte or the causative organism of the disease. Baldwin⁶ later reported a similar case—that of a young female patient suffering from a phthisis-like illness and achalasia of the cardia, in whom a bacillus was isolated, resembling the strain of "M" bacillus; his patient, like that of Cummins and Williams, was completely restored to health. Of special interest is the description by Neisser⁷ of acid-fast bacilli found on practically all metal medical instruments, but less frequently on wooden ones.

CONCLUSIONS

The above considerations prompt the following practical conclusions:

1. A diagnosis of pulmonary tuberculosis based on a single positive direct sputum examination without any other evidence is not justified.

2. In any case, whenever possible, more than one sputum examination should be carried out.

3. In view of Cummins and Williams's and Baldwin's cases it would appear that "even when the clinical picture is convincing, the finding of acid-fast bacilli in the sputum is not necessarily proof-positive of tuberculosis. The importance of cultural verification in all doubtful cases cannot be too much stressed" (Cummins and Williams).

4. When there is any question of compensation, pension, etc., unless the clinical picture is quite clear, not only should more than one sputum examination be carried out, but the patient should be made to expectorate in the presence of the physician or pathologist, and, if necessary, after isolation in a hospital ward under observation.

5. It would be well if the practice were universally adopted of indicating in every sputum report an approximate estimate of the number of tubercle bacilli present—for example, twelve per field, one per four fields, etc.

Clinical Memoranda

SEVERE HAEMORRHAGE WITH SPONTANEOUS EVACUATION OF PERITONSILLAR ABSCESS: LIGATION OF COMMON CAROTID—RECOVERY

I have read Dr. P. Shackleton's two cases of pharyngeal haemorrhage, published in the *Journal* of December 23rd, 1933, with much interest. Severe haemorrhage from a tonsil abscess is, as Mr. E. D. D. Davis remarks,¹ rare, and I think the following case should be added to those already on record.

CASE REPORT

The patient, a sturdy, full-blooded brewery labourer, now aged 46, gave a history of having been troubled by tonsillitis all his life. On April 3rd, 1929, he retired to bed with "influenza" and a sore throat. The sore throat settled on the right side, and four days later an "abscess on the right tonsil" burst, giving him considerable relief. At 1 p.m. on the following day he felt a "hot, tingling sensation" in the back of his throat, and suddenly found his mouth full of blood, which, he said, he had to spit out quickly, otherwise he would have choked. This bleeding stopped in a quarter of an hour, but recurred alarmingly a few hours later, when Dr. A. T. McKay had him admitted to Mercer's Hospital under the care of Sir John Lumsden and myself.

On admission the haemorrhage ceased for a day, but the next morning the patient suddenly spat up a kidney-trayful of blood. Examination of the throat at this stage revealed a resolving quinsy, and I tied off what I thought to be a bleeding point low down on the posterior pillar. This had no effect, however, and haemorrhage continued at intervals throughout the following day, in spite of all our efforts to control it with tonsil clamps, haemostatic injections, and other agents. On the evening of the third day after admission the patient had become very bloodless indeed, and as his condition was obviously serious it was decided to tie the right common carotid artery. This was accordingly done under very light ether anaesthesia. Just before the anaesthetic was started the patient vomited up two pints of fresh clotted blood. This very nearly proved the last straw, for although blood transfusion was performed as soon as possible after operation, and again after an interval of two days, the patient's condition continued to be very critical indeed for several days. He told me afterwards that during this period if either arm fell out sideways from the bed he had not the strength to move it back again. He noticed this particularly

on the second day after operation, when the weakness could not possibly have been due to the very light anaesthetic. A very slight bleeding from the throat occurred on the fourth day after ligation of the artery, but apart from this recovery was progressive and uneventful. The patient was discharged from hospital after four weeks, and to-day his only complaint is that he is getting too heavy. He has not had a sore throat since.

Haemorrhage, such as occurred in this case, is unique in my experience as a laryngologist. The patient was as profoundly drained of blood as a bad case of placenta praevia or post-partum haemorrhage. The exact pathology is unknown, owing to the happy termination of the case and the method of operative treatment, but such bleeding could only have been due to the erosion of a large vessel.

The important fact to be noted is that incision of the abscess was not carried out, since the patient did not call for medical attention until after the abscess had burst spontaneously; consequently it cannot be held responsible for the haemorrhage. Dr. Shackleton's first case, the present one, and one or two others,² show that incision is by no means always to blame for the occasional severe bleeding which occurs with peritonsillar abscess. In fact, as StClair Thomson says,³ these cases demonstrate rather that the abscess should be opened in good time. As is to be expected, in the greater number of recorded cases the abscess has been incised. In a series of cases of severe haemorrhage associated with the opening of a quinsy recorded by J. E. Newcomb⁴ twenty-eight out of fifty-one patients died, a mortality of 54.8 per cent. The common carotid was tied in sixteen of these fifty-one cases with eleven recoveries, a figure which suggests that the line of treatment adopted in the present case, although drastic, is efficient. Nevertheless, should I be unlucky enough to meet another similar case, I think I shall dissect out the tonsil and look for the bleeding vessel in its bed. Ligation of the common carotid is rightly regarded as rather an extreme measure, but one need have no hesitation in carrying out the former procedure at the first sign of bleeding. If it fails, the carotid can still be tied.

ACUTE MERCURIAL POISONING

The following clinical notes on a case of acute mercurial poisoning may be worthy of publication. They have a forensic as well as a clinical interest.

CLINICAL HISTORY

The patient was a married woman, aged 27. On October 19th, 1933, menstruation being then a day late, the patient, fearing she was pregnant, contrived a vaginal douche with some "tablets" left from the previous confinement by her attendant. These were stated to be tablets of mercuric chloride, containing a little over 7 grains in each. One of these tablets was dissolved in "a little over a pint of warm water and applied with a rag." No proper form of douching was given, and nothing was inserted up the vagina. The liquid immediately produced a great sensation of burning, and its application was stopped. Three hours later the patient collapsed while at work about the house. Palliative treatment was applied locally, and she was treated for shock. She commenced vomiting soon after her collapse, and this continued for the next three days. The day after the onset the patient had passed no urine, had not slept that night, and was complaining of intense burning pain in the vagina and

lower abdomen. At this time menstruation began, and simultaneously she had frequent passage of small fluid motions. These motions were blood-stained. The day after this (the third day after the onset) she became worse; suppression of urine had continued, and her motions were now almost pure blood. She was admitted to hospital.

Her condition on admission was one of lethargy, and her mental condition was abnormal. She denied being in acute pain, and complained chiefly of sleeplessness. There was marked fetor oris. The eyes showed a small subconjunctival haemorrhage in the left outer canthus. There were some teeth missing, and a few were septic. The gums were healthy. The lungs and heart were normal. The abdomen was markedly tender in the renal angle posteriorly, and at the outer border of the rectus sheath anteriorly at the level of the umbilicus. The vagina was much inflamed, especially about the vestibule; a copious blood-stained discharge was present. The parts were acutely tender on examination. The bladder was empty. A few ounces of sterile milk were passed into the bladder by means of a catheter, but were retained, and there was no sign of a vesico-vaginal fistula. The milk was then drawn off, and was slightly blood-stained.

The vaginal discharge and the frequent motions continued throughout. There was no further vomiting after the first day in hospital. The day after admission burning in the mouth was complained of, and also a sore throat. A patch of buccal mucous membrane opposite the third molars on the left side was seen to be covered with a foul greenish slough; this gradually spread, and after three days the mouth was extensively ulcerated with similar areas, involving the soft palate and the nasopharynx. A blue line, beginning round the septic teeth, appeared on the second day, and gradually spread. The vagina at this time showed a large shallow ulcer on the posterior wall. A self-retaining catheter was inserted, and drained three ounces of dark, bloody fluid. The same night she began to suffer from intractable hiccup. The next day (the third after admission, the sixth after the onset) her blood urea was 301 mg. per 100 c.cm. blood. She began to cough up a quantity of foul sputum, and the chest on examination revealed numerous moist rales all over both lungs. The fourth day after admission the eyelids and face were swollen, and the mental condition of lethargy became somewhat worse. At 11 a.m. she complained that her feet were heavy and numb and that she was unable to move her legs. At 4 p.m. she was unable to move her legs or arms. Respiration became laboured. Examination showed a complete flaccid paralysis from the waist down; sensation was impaired but not lost. At 7 p.m. she became cyanosed, the tongue began to protrude, and the patient presented an appearance as if she were being strangled. She was still conscious at this stage, but respirations became gradually weaker, and she died fifteen minutes later.

PATHOLOGICAL FINDINGS

Post-mortem examination revealed extensive ulceration of the nasopharynx, which was covered with a greenish slough; this was removed with difficulty, leaving a raw area. The oesophagus and stomach were normal. The small intestine showed reddening of the mucosa. The whole length of the colon showed an intense haemorrhagic inflammation. The liver was natural on gross examination. There was some catarrh in the lungs, and the heart was healthy. The bladder was empty and appeared natural. The kidneys were large and the perirenal fat was greatly distended, presenting a jelly-like appearance, something like washing-starch. The capsule stripped easily and the cut surface bulged. Otherwise there was no gross abnormality in the kidneys. The genital organs, removed entire, showed no evidence of injury. The vagina was ulcerated in a patchy manner and extended high up into the posterior fornix within 1 inch of the cervix. The uterus contained a little menstrual blood, but was otherwise normal. Microscopically the liver showed cloudy swelling and the kidneys an acute glomerulo-tubular nephritis, the striking feature of which was that the straight collecting tubules had escaped, and could be plainly seen running through the diseased parenchyma.

The inquest was held without a jury, and the coroner returned a verdict of "Accidental death."

BARON RUSSELL, M.R.C.S., L.R.C.P.

Gravesend Hospital, Kent.

give a course of lectures to the students of University College, London, in 1933; these lectures form the basis of the book under review. Dr. Gregory has spent his busy life in tracing the evolution of the higher vertebrates, particularly the highest of all—the primates—from evidence gathered from an examination of their fossil remains. In determining the relationship of fossil forms of man and of ape to each other and to their living representatives Dr. Gregory has had to depend on the evidence of the teeth—for teeth and jaws are the parts of the body which best resist the disintegrating action of the soil. The points in which the teeth of extinct forms of humanity and of extinct genera of anthropoids are in agreement are so numerous and so intimate that Dr. Gregory finds it hard to discover a criterion which will serve to distinguish an anthropoid from a human tooth. A structural resemblance of so close a nature can be explained, so Dr. Gregory believes, only by supposing it to be an inheritance from a common ancestor. Professor Wood Jones, on the other hand, believes that anatomical similarities may represent not a common but an independent or separate inheritance. The similarities between man and the anthropoids are, however, too numerous and too intimate to be explained as independent inheritances. Dr. Gregory cites the conclusions reached by Professor J. P. Hill of University College, London, after an elaborate investigation of the placenta of all higher vertebrates. The human placenta, Professor Hill found, repeats with wonderful accuracy the structural details found in great anthropoids. In their susceptibility to disease, and in the reactions of their blood, the great anthropoids are almost human.

The four plates which illustrate this work are particularly worthy of note, not only for their artistic finish, but also for the sharpness of the impression conveyed. They give in diagrammatic form the best that is known concerning the evolution of man and beast.

PRACTICAL THERAPEUTICS

When reviewing Professor DAVID CAMPBELL'S *Handbook of Therapeutics* in 1930 we expressed appreciation both of the author's very practical purpose and of the thoroughness with which this purpose was pursued. We ventured the anticipation that the volume had a distinct opportunity for service, and the appearance of a second edition* appears to justify this conclusion. The book remains a most helpful guide in the art of medical practice in so far as this is concerned with the use of drugs, sera, and vaccines, with the choice of diets, and with the application of electricity and other physical agents, although in this last-mentioned section there is no pretence of technical completeness. The therapeutic demands created by disease of the various organs and systems of the body are described in considerable detail, and here the author, speaking largely from personal experience and first-hand knowledge, may well command the confidence of the student, for his judgements are expressed with decision but without undue dogmatism. Not that every physician would endorse all these judgements. For example, is it to be accepted that for free haematemesis "operation is the only treatment, and is best performed at the earliest possible moment"? Or, again, that in apoplexy in a plethoric patient venesection is of doubtful value, while a preferable proceeding is to remove some of the cerebro-spinal fluid by lumbar puncture? Professor Campbell seems to have little faith in blood-letting,

except, possibly, in hyperpiesis, and neither "leeches" nor "venesection" appears in his index; he gives no directions for opening the vein, although blood transfusion and intravenous injection receive full notice. For the latter method he figures the arm strangled by a piece of rubber tubing, whereas the armlet of the sphygmometer is much less uncomfortable for the patient, much more readily controlled by the operator, and is, we imagine, generally adopted.

The new sections of the second edition refer to the treatment of coeliac disease and of sprue; to the use of nirvanol in chorea, of suprarenal extracts in Addison's disease, and of carbon dioxide as a respiratory stimulant; also to a few other recent therapeutic proposals. To all these suggestions the author applies a critical, but not an unappreciative, judgement, and here, as in the rest of his book, he renders substantial service both to the art of medicine and to those who practise it.

VENEREAL DISEASES

The fifth edition of Mr. WANSEY BAYLY'S little book *Venereal Disease: Its Prevention, Symptoms and Treatment* contains some additional matter on pathological diagnosis and treatment, and a short section on "The Law and Venereal Disease." If the author merely had indicated the means of prevention and avoided dialectics he would have had more space for subjects such as the complement-fixation test in gonorrhoea, kinds and dosage of vaccines, the importance of cultures, and some mention of such entities as lymphogranuloma inguinale and granuloma venereum. On the whole the teaching is sound, but the treatment of syphilis is somewhat less than that advocated by most modern syphilologists. Many of the statements are highly controversial—for example, the Vernes test, which is lauded, did not show up very well in a comparison with others at Copenhagen. Again, "chancroid" is not the name applied "to all non-syphilitic ulcers found on the penis and vulva whatever the causal organism may be"; many observers think that gonorrhoeal proctitis in women is relatively common, not "rare"; most people find intramuscular mercurial injections rather painful; and the curved Kollmann dilator (illustrated) is rather a weapon of torture than an instrument for treatment. Further important omissions are the prevention of post-lumbar puncture headache—which may be accomplished by the use of Colonel L. W. Harrison's fine needle—and the use of the Dmelcos vaccine in the treatment of chancroid; whilst non-gonococcal urethritis, very common nowadays, receives scant attention.

The book is said to be written for students and general practitioners; these would appreciate detailed information about the urethroscope more than a long description of Bellfield's operation—which they are never likely to perform. Like the peers in *Iolanthe*, the author makes "no pretence . . . to scholarship sublime," for he splits infinitives with gay abandon, and errors in grammar are all too frequent, while some sentences are almost unintelligible; perhaps the proof-reader should be blamed for "curvature" instead of "curative," and "systematic" for "systemic." Three coloured plates are works of art, and most of the illustrations are good; the book is bound and printed well, but its contents are capable of improvement, and it is not a suitable work in which to boost the policy of the Society for the Prevention of Venereal Disease.

NOVA ET VETERA

THE HEALTH OF THE NAVY 150 YEARS AGO

The two greatest ships of the Navy are the *Nelson* and the *Rodney*. Nelson we all know; his predecessor Rodney is less famous, though he did useful work when young, and in his last command, in the West Indies, beat de Guichen in 1780 and de Grasse (whom he captured) in 1782, this latter when England had particular need of a victory as an encouragement. Yet, even so, it may be held that Rodney's best and most enduring influence on the Navy was the outcome of his delicate health which made him take with him a private physician to the West Indies, one Gilbert Blane, M.D., of Glasgow, to become the effectual founder of the science of naval hygiene. Pleased with Blane's professional skill and personal bravery Rodney made him Physician to the Fleet, comprising at that time twenty-six ships of the line and 12,000 men, of whom died in a year 1,577, only fifty-nine in battle or from wounds, a terrible mortality of about 125 per 1,000 from disease.

At the end of 1781 Rodney had to go home for an operation, taking with him Blane, who presented a memorandum of needed improvements to the Admiralty, asking for fruit and vegetables to stop scurvy, wine instead of rum, Government supply of medicines, dry ships, special food for the sick on board so that they need not all be sent to the hospitals, in which no one should have less than 500 cubic feet of space. These proposals, backed by Rodney, were approved, and Blane returned with his admiral in the *Formidable* in 1782 for Rodney's famed victory of "The Saints." When in August Rodney after his victory went home, Blane remained with Admiral Pigot until the end of the war in 1783, so he had three summers of experience in the largest fleet that had ever yet been sent abroad. The effect of his approved proposals was immediate. Rodney said that in his flagship "of 900 men not one was buried in six months" (those immediately following); in the fleet Blane tells us (*Diseases of Seamen*, p. 200) the mortality was halved before the end of the war in 1783.

We are led to speak of Blane at this moment through seeing, in the *Journal of the R.N. Medical Service* for October, 1933, an abstract by R. R. Jones of the very interesting log of a surgeon who sailed in the *Formidable* with Blane and Rodney in January, 1782. The log is unsigned, but the author was probably Nath. Bedford of St. George's Hospital, and a credit to the teaching of John Hunter. He mentions Blane and Rodney each only once, but though a novice his practice is along lines Blane advised, so he knew wisdom when put before him. Scurvy was the chief anxiety, and he notes on the way out, "Our small beer lasted all the month, so that we had not a single scorbutic symptom," but the venereal list "was crowded, from the women we had on board by the admiral's desire, to attend the sick." After the battle he was sent to *Ardent*, a French prize, where he found "a most noisome stench" and always a third of her crew ill with fever. In May he was promoted to the *Conqueror*, where his chief troubles were with fevers, fluxes, and scurvy. Fevers, very violent, attacked men sent ashore to get wood and water, fluxes were fewer if cases were segregated and care taken to clean the buckets after each stool, scurvy was easier to prevent by fruits, malt, and beer than it was to cure. One man died of ulcer after "an accidental Haemorrhage induced by hitting his foot against a bucket"—by kicking a bucket, in fact. The treatment of the injuries he reports was more successful than one would have supposed likely in days so far pre-antiseptic: a "cut throat, trachea divided and both carotids exposed," healed and went to duty in five weeks. Tetanus was a great trouble after wounds in action. The opinion of Admiral Pigot in note 5, p. 240, is quite at variance with Blane's, who notes that his "great zeal for the service, as well as his natural humanity, induced him

to listen to whatever was proposed for the benefit of the men" (p. 145, loc. cit.). Here Blane mentions thirty casks of limes given to cases of scurvy that "proved of infinite use," and on page 54 that in two ships at Montserrat "a few bushels of limes," their only refreshment, cured 174 cases of scurvy in twelve days. The juice of limes as a cure for scurvy is now suspect, but it then had much clinical evidence in its support.

At home Blane was elected physician to St. Thomas's Hospital, persuaded the Admiralty in 1795 to make lime juice an issue, which entirely banished scurvy, was appointed physician to the Prince of Wales and later to King William IV, in 1821 was presented by medical officers of the Navy with a piece of plate, and in 1829 established the Blane medal. In every family of his descendants one son was always called Rodney, but alas! the last baronet was lost at Jutland.

BEETHOVEN'S DEAFNESS

It is a fairly well known fact that Beethoven was afflicted with deafness, and the appreciation of his genius is enhanced by the knowledge that many of his greatest works are those of an almost completely deaf man. We will not consider here the influence of his deafness upon his compositions and personality, except, in passing, to observe and wonder at the greatness of his spirit which triumphed over this crushing infirmity, bringing him "joy through suffering" and allowing his genius full scope.

From the medical point of view Beethoven's deafness presents an interesting problem in diagnosis, and we have been provided with enough evidence by Beethoven himself and his contemporaries to enable us to make a very fair guess at its nature. In his will (dated 1802) Beethoven states that his deafness first appeared six years previously—that is, in 1796, at the age of 26. At first it was slight, and he was able to conceal his infirmity, but it became progressively worse until it was finally almost complete. After 1816 it was so marked that he could only communicate with his friends by getting them to write in conversation books, and in 1824, after conducting a performance of his Choral Symphony, he was quite unaware of the applause that was being given him until one of the performers took him by the hand and turned him round so that he could see the audience clapping and waving.

From the first he suffered from tinnitus, which caused him great annoyance and sadness, and he appears to have heard low tones better than high ones. Writing to his great friend Dr. Wegeler in 1801, Beethoven says: "I cannot hear the high notes of the instruments or the voices if I am but a little distance off. When anyone speaks quietly I only hear with difficulty; on the other hand, I find it unbearable when people shout to me." These two observations are extremely pertinent from the medical point of view. The first—diminished perception of high tones—is, by itself, a feature of nerve deafness; the second it would seem only reasonable to interpret as a manifestation of paracusis, which is characteristic of conduction deafness.

In his last years, as an aid when composing, Beethoven used a wooden rod, one end of which was placed in the sound box of the piano and the other held between his teeth. This clearly suggests that, in his case, bone conduction was better than air conduction, which again is a feature of middle-ear deafness.

Most of the available evidence suggests that Beethoven's deafness was middle-ear in origin, and the history of progressive deafness coming on in early adult life and accompanied by tinnitus would fit in well with the clinical type now known as otosclerosis. The one definite indication of nerve deafness—diminished appreciation of high notes—suggests that a certain degree of this type of deafness may have been superadded, which is a not uncommon occurrence in otosclerosis.

THE ARTIFICIAL MENOPAUSE

Woman is called upon to pay a big price for her privilege of being charged with the major responsibilities for perpetuating the race. Her reproductive period ended, she has to face the troubles of the "change of life," which vary both in kind and in intensity, which may persist for many years, and which have but one consolation—that menstruation and child-bearing are over. The family physician is not as a rule burdened with large numbers of these sufferers, because, fortunately for him, woman has long believed that these and other ills resulting from childbirth are inevitable, and form part of her destiny. During the last three decades the problem of the artificial menopause has obtruded itself, and there is no doubt that the symptoms following surgical castration may be more severe than those which follow in the course of nature, and are sometimes alarming. The operations of ovariectomy and hysterectomy have been rendered so simple that the general surgeon has not hesitated to invade the pelvis without regard for the conservative, often more difficult, and always more tedious, technique elaborated by gynaecologists. Then, too, x rays and radium arc being used more and more in the treatment of uterine haemorrhage, and whereas ovariectomy is often incidental to the main object of the surgeon, the destruction of ovarian tissue is the primary object of the radiologist. There is one further aspect of the whole question which must of necessity assume an increasing importance. A greater number of women are finding places in the professions and in industry, and they naturally tend to achieve success and control of others at about the time of the menopause. Now the associated physical changes may obviously make such women incapable of exercising their duties in a manner which their previous service would seem to have assured.

It is a slur on medicine—possibly because women have been fatalistic rather than importunate—that little or nothing has been done to relieve such sufferers. It is therefore of significance that the eighth Congress of the Association of French-speaking Gynaecologists and Obstetricians chose the artificial menopause and its treatment¹ as the special subject for its discussions, and invited L. Brouha, A. van Cauwenberghe, P. Lamarque, G. Massabau, and A. Guibal to contribute the main papers. L. Brouha epitomized the results of castrating animals, discussed the latest work on the sex hormones, and indicated the influences such discoveries might have on therapeutics. A comprehensive review of the effects produced by the surgical and radiological castration of women was presented by

van Cauwenberghe. Castration before puberty is but rarely necessary, and the small number of cases reported show that it leads to imperfect development of the breasts, the uterus, external genitalia, and pubic hair, while the woman tends to become tall and presents a masculine or eunuchoid appearance. After puberty castration affects the metabolism and leads to physical and psychical disturbance. The basal metabolic rate is lowered, as is the tolerance to carbohydrates, while an increase in the weight of the body and in the systolic blood pressure is frequently noted. Of the physical troubles the most important are: flushings of heat and cold, and other symptoms dependent on disturbances of the vasomotor system, which may result in congestion affecting the eyes, ears, kidneys, intestines, bronchi, and liver. Headache is common, as are nausea, pain in the bones, arthralgia, and arthropathies affecting the larger joints. Finally, several affections of the skin, such as pruritus, eczema, erythema, fugitive oedema, and hypertrichosis may occur. The psychical disturbances vary from a slight change in character through melancholia stans to insanity, the more severe forms arising in between 1 and 2 per cent. of cases. The sexual appetite is no criterion of gonadic activity, and is not seriously diminished in the majority of cases, and may even become increased. The time of onset of the symptoms varies, and they may not become evident until two or three months after the operation, and are apt to cause the maximum disturbance at those times when the menstrual periods would normally have occurred. The duration of the symptoms varies from a few months to several years. It will be observed that the artificial differs from the natural menopause only in the abruptness of the onset and (particularly in young women) in the severity of the symptoms. The symptoms following irradiation of the ovaries naturally vary with the dosage employed and the degree of damage inflicted, but are usually less severe than those following surgical castration.

The variety of the treatments advocated testifies to their inadequacy; they include hypnotic drugs, calcium, snake venom, irradiation of the thyroid and pituitary glands, and hemithyroidectomy. The extravagant claims made on behalf of folliculin are somewhat shaken by the extraordinary variation in the dosage used, and by the fact that the majority of authors claim good results when the hormone is given by mouth. The wide differences in the technique employed make it difficult to assess the merits of ovarian grafts, but they have not proved as successful as might have been anticipated. Van Cauwenberghe concludes that hormonal treatment following surgical castration will give the best results if it is reserved for patients who are not too young and if it is commenced shortly after the operation. Small doses should be injected intramuscularly for eight to ten days each month at the times the periods should have occurred, in conjunction with medical, physical, and psychological treatment. Paul Lamarque, after a review of the literature dealing with temporary sterilization by x rays, concludes that

¹ *Gynéc. et Obstet.*, 1933, xxviii, Nos. 3 and 4.

the procedure is unsatisfactory because it is impossible to gauge the required dosage with sufficient accuracy, and because even when the end is achieved the period of amenorrhoea is too uncertain. So much has been written lately on the function of the pituitary gland in controlling the ovaries that the contention of Massabuau and Guibal that there is a synergistic association between the uterus and the ovaries appears heterodox enough to be interesting. They point out that removal of both ovaries does not always cause amenorrhoea, and that cystic changes frequently take place in the ovaries after the uterus has been removed. Further, it has been observed that ovarian grafts "take" much more successfully if the uterus has been left behind. The two latter contentions may, however, be explained by the fact that, according to some anatomists, the uterine arteries supply the major portion of the blood to the ovaries, and this supply is of necessity cut off if any of the usual operations of hysterectomy are performed. These authors therefore advocate that as much uterine tissue as possible be conserved, and thus come into conflict with the view so ardently championed by Herbert Spencer, and fast gaining ground in this country, that when hysterectomy is performed the whole uterus should be removed. English gynaecologists will probably be more impressed with the danger of cancer developing in the cervical stump than with the hypothetical value of a few square centimetres of uterine mucosa to the ovaries.

One very important aspect of the question not referred to by any of the speakers at the French Congress is whether menopausal symptoms vary significantly with birth and race. It is a common belief that highly cultured, sensitive women are more liable to suffer severely as the result of surgical castration than average hospital patients, and if this is true significant differences might be observed as between the Latin and Northern races. These papers, with their very full references to the literature and the subsequent discussions, have furnished perhaps the most valuable account of the artificial menopause so far recorded. Even if the present treatment of the condition is shown to be unsatisfactory, a stimulus is given to further study. Disappointment at the results of hormonal therapy will be mitigated once the idea is grasped that if the ovaries suffer all the endocrine glands suffer with them.

NEGLECTED CHILDREN IN AMERICA

The children of the United States of America must now be used to seeing themselves described as those "whose faces are turned toward the light of a new day and who must be prepared to meet a great adventure." It would be interesting to learn whether they know what this means, or what impression, if any, the reiterated description has made upon them. For there has been time: they have not been the same children. The White House Conference of 1909, with its portentous production of platitudinous resolutions in the form of "The Children's Charter," appears to

have initiated the attitude and suggested the description. Ten years later a second conference confirmed the opinions of the first. And now, as the result of a third conference held eleven years later still, and as the outcome of the labours of hundreds of persons combined in associated committees over a period of a quarter of a century, we have the official publication of a large volume on *Dependent and Neglected Children*,¹ which re-echoes the description of American children and reconfirms the opinions previously expressed. Following a general report adopted by the executive committee in plenary session, the book contains an abundance of subsidiary reports, resolutions, addresses, and memoranda; the whole material, with copious bibliography and index, occupying 448 pages. It may be doubted whether this repeated enunciation of truisms, after immense labour and at great expense would be tolerated by the White House under conditions more recently established there.

Such, however, appear to be the now recognized American methods and procedure, and it must not be supposed that they are entirely without some useful or suggestive results, though, in the main, the conclusions set forth are essentially the same as those reached long ago in this country by less laborious and more common-sense effort. One may ask why the word "dependent" appears in the title. Is it not of the very essence of childhood to be dependent? One may ask, again, whether it is really necessary or helpful to keep repeating the statements that children of decent parents and deserving mothers should be kept at home, that every child should receive the best medical attention, and that local child-caring agencies should co-operate? Yet there are scores of conclusions and recommendations of this kind set out at the end of the various sections into which the report is divided. One can only suppose that they are the result of "the opportunity to develop and harmonize different points of view on policies and methods" which the committee claims is "one of its major contributions to the field of child welfare."

Nevertheless, if there is no very practical or concrete outcome easily apparent from the whole business, the wide and complete survey over a great field may serve to bring home to an intelligent but not very thoughtful community the shortcomings of its provision for child care, the general need for effort and the main directions in which effort is needed, and the nature and extent of the progress that has been made since the year of the original White House Conference. Those, too, who in our own country are urging the enactment of a new method of preventing procreation in the case of persons who, they believe, are unfitted for parenthood, may well have their attention called to the comprehensive tabulation and review in this volume of the numerous causes of child neglect in the home other than backwardness of mind in a parent.

THE MELBOURNE MEETING, 1935

September, 1935, is a long way ahead, but Australia is a long way from Britain, and we need make no excuse for reminding members in April, 1934, that the 103rd Annual Meeting of the British Medical Association will be held in Melbourne next year, and that those who think of attending it should lay their plans well in advance. The Council is most anxious that the number taking part in the first meeting of the Association in Australia should be as large as possible. With this end in view steps have been taken to combine with the voyage to Melbourne an attractive "round-the-world" tour. Particulars of routes, prices, etc., were given in the *Supplement* to our issue of March 10th. All arrangements in connexion with the journey are in the hands of the Financial Secretary and Business Manager, to whom early application should be made for further details, and for reservation of places on steamers and trains and at hotels. Arrangements have been made for members who cannot afford to be away for the whole time of the tour, but who may wish to attend the meeting, to leave London on August 8th, travelling overland to Toulon and embarking there on a P. & O. liner which arrives at Fremantle on September 3rd. The journey on to Melbourne takes three days by rail, so that members travelling by this route will reach their destination on September 6th, three days before the commencement of the meeting. Sir Richard Stawell, consulting physician to the Melbourne Hospital, has been nominated for the presidency. The scientific work will be divided among fourteen Sections. On the social side those responsible for organizing the programme are making every effort to ensure that the event shall be worthy of the occasion, and a very warm welcome may be counted on from our Australian colleagues. The honorary local general secretary of the meeting is Dr. J. P. Major, Medical Society Hall, East Melbourne, Victoria.

"THE HYPERERGIC STOMACH"

In a recent paper¹ K. Westphal alludes to the changed conceptions of the pathology of the gastro-duodenal mucosa which have been introduced recently as a result of histological examination of resected operation specimens, new radiological methods, and gastroscopy. Protesting against the tendency to label all non-ulcerative lesions as "gastritis," he points out that in many there is increased, not lessened, function, and that clinical evidence of gastric or extra-gastric inflammation is absent. In a series of 400 in-patients examined clinically and radiologically, all of whom had a symptom-complex pointing to ulcer, 244 had duodenal ulcer, 75 gastric ulcer, and 129 no ulcer. To the third-named group of cases the name "hyperergic irritable stomach, Grade I," is applied: the patients are comparatively young and have a short gastropathic history. Their gastric juice is moderately hyperacid, and radiologically the folds of mucosa are steep, tortuous, and usually somewhat broadened. From Grade I there may develop Grade II of the "hyperergic, irritable stomach," with broadening of the mucosal folds up to a fingerbreadth, and good preservation of secretion. Grade II findings are present

also after intoxications (nicotine, lead), and in 60 per cent. of gastric and 50 per cent. of duodenal ulcers. As a result of intensive alkali therapy the hyperergic stomach not infrequently becomes the site of chronic gastritis, with morbid cellular changes in the secretion. Its broad high folds, however, are due not to gastritis, but to purely functional alterations (probably in part neurogenic) of the muscularis mucosae, blood supply, and interstitial cell content. Examination of the cell content of the gastric juice shows that increased cell exudation and increase of leucocytes are absent in nearly all duodenal and in one-half of gastric ulcers, and in the hyperergic stomach. Concerning treatment of chronic ulcers, Westphal concludes that this must aim at diminishing the motility of the mural and mucosal muscle (atropine medication), the gastric acidity, and the cell diapedesis from the capillaries of the mucosa. The last two aims are best achieved by giving 5 to 10 c.cm. of olive oil twenty to thirty minutes before meals. Westphal's recent experience has proved the efficacy of this in a large series of peptic ulcers.

THYROIDECTOMY IN HEART DISEASE

The excision of a healthy organ as a remedial measure for disease in another organ is an unfamiliar expedient in modern medicine. In fact, such a procedure could only evolve from increasing knowledge of the intimate physiological and pathological relationships between one system and another. A therapeutic measure along these lines has lately been advocated by Levine, Cutler, and Eppinger,¹ who have claimed that total thyroidectomy may bring considerable benefit to patients suffering from advanced heart disease in whom other remedies have been unavailing. The clinical records contained in this work constitute the extension of a previous publication on the same theme,² and the principles underlying the procedure are based upon the study of thyrotoxic heart disease. Attention has often been called to the astonishing benefit produced by subtotal thyroidectomy in thyrotoxic heart disease. Further, it has commonly been observed that this operation is of great value when thyrotoxicosis complicates unrelated heart disease, such as mitral stenosis. More recently it has been determined by Morris³ that disease of the heart may owe its origin to obvious disturbance of thyroid function, while the basal metabolic rate remains normal; to go a step further, certain cardiac abnormalities such as auricular fibrillation may be due to occult thyroid influence, the true basis of the cardiovascular fault only being disclosed later. In such cases subtotal thyroidectomy has often brought about great improvement. These results suggest that disease of the thyroid must have deleterious effects upon the circulation other than those due to increased metabolism; an additional corollary (which is the source of the new procedure advocated by Levine) is that excision of the healthy thyroid may, by lowering the rate of metabolism, unburden to some extent a severely damaged heart. Levine and his associates have observed the results of partial or complete thyroidectomy in twelve patients suffering from the most severe forms of heart disease. The group consisted of

¹ *New England Journ. Med.*, 1933, ccix, 667.

¹ *Zentralbl. f. Chir.*, February 17th, 1934, p. 370.

valvular heart disease with auricular fibrillation; angina pectoris, and non-valvular congestive failure in equal proportions. In view of the more or less experimental nature of the method, the selection of cases was limited to those gravely crippled and unrelieved by other measures. In six of the patients considerable improvement followed the operation, in three only moderate or slight benefit resulted. It was at first thought advisable to perform a subtotal thyroidectomy, but it was found that the reduction in metabolic rate following this operation was often only transitory. Complete thyroidectomy was adopted in subsequent cases as a means of overcoming this difficulty. Such procedure was usually followed by a reduction in metabolic rate to the neighbourhood of -20 per cent. In most patients thus treated the maximum slowing of metabolism was only reached after some weeks, and in some of them the symptoms of myxoedema supervened, but were satisfactorily controlled by thyroid medication. The beneficial influence of thyroidectomy in chronic heart failure is not difficult to understand when we remember that slowing of the circulation is an integral part of congestive failure. While the sluggish circulation may be inadequate for the needs of normal bodily metabolism, it may suffice to meet the requirements of the body when the metabolic rate is lowered. How thyroidectomy favourably influences angina pectoris is more difficult to understand, for in this condition the circulation is not usually impaired. It has been suggested that the effect of thyroidectomy upon angina is in some way related to reflex or humoral alterations possibly connected with the activity of the suprarenal glands. These observations have opened up new possibilities in the treatment of patients who have hitherto been regarded as hopeless cardiac cripples. It may be that a further lease of life and comparative comfort can be secured for such sufferers, but it goes without saying that an irreparably damaged heart can only gain temporary respite by these measures. How far the operation of thyroidectomy for heart disease and failure will become a useful and practicable proposition remains to be seen.

SHOULD DIABETES BE NOTIFIABLE?

Discussing the high mortality and morbidity rate in diabetes F. Meythaler¹ comes to the conclusion that it is less the constitutional factors in the patient himself than external circumstances which are responsible for such high figures. According to this author, the non-constitutional factors adversely influencing the course of this disease may be classed under four headings: (1) non-observance of medical advice owing to economic reasons; (2) insufficient expert knowledge of the medical adviser and his failure to establish a correct diagnosis; (3) the fact that the patient is not conscious of being really ill, and therefore neglects to observe the irksome restrictions put upon him; and (4) dangers accruing from the transition of the patient from hospital to home care. Basing his argument on his experiences as head of a special diabetes out-patient clinic in Bonn, Meythaler contends that the influence of these factors might be considerably lessened, and the mortality and morbidity rate reduced, by making diabetes a notifiable

disease and organizing special diabetes out-patient clinics all over the country. Beyond keeping the patients constantly supplied with a sufficient quantity of insulin, these stations would exercise constant supervision over their condition, develop prophylactic measures against diabetes, and ensure that sufferers from the disease should be kept out of professions where, owing to their disability, they might endanger others.

THE USE OF LEISURE

In his presidential address to the British Association Sir F. Gowland Hopkins said: "I confess that if civilization escapes its other perils I should fear little the final reign of the machine. We should not altogether forget the difference in use which can be made of real and ample leisure compared with that possible for very brief leisure associated with fatigue; nor the difference between compulsory toil and spontaneous work." The machine has introduced many complications into the modern world, and not the least is the problem of how human beings are to employ the leisure that is being, and will increasingly be, thrust upon them. To the busy practitioner of medicine, however, leisure has the same elusive quality as the philosopher's stone. He may seek for truth, and even for beauty, but to dally along primrose paths, he knows, is not for him. Yet, concerned as he is with the mental and bodily health of the community, the way in which other people use their free time has some bearing upon his professional activities. The problem must have presented itself very forcibly to the minds of doctors in the depressed industrial areas. The atrophy of mind and body brought about by prolonged unemployment is not one that can be remedied by a bottle of medicine, and the suggestion of good times to come has all the limitations of a not very effective placebo. An attempt to solve the problem, not so much of unemployment as of leisure, was made in 1932, when the Grith Fyrd Camp was set up at Godshill.¹ Another camp has recently been established at Alderwasley, near Ambergate, in Derbyshire. These camps are run by young men of all classes who are out of work. (It is hoped to extend the camps for women and married couples.) They aim at making the camp a self-supporting co-operative unit, and pay into it—if technically unemployed—the whole of their unemployment or transitional benefit. They fell trees, build houses, bridges, and roads, grow their own foodstuffs and rear live stock, and occupy themselves with such handicrafts as weaving and thatching. In this scheme the idea of charity is abolished, and the money-making motive is eliminated. The camper, working with his own hands to supply not only his own needs but the needs of his community, learns to live in order to work, instead of working just in order to keep body and soul together. The value of such a scheme must be immense, for it restores self-confidence and pride of person in men who have suffered from the degradation of enforced idleness. Primarily it is an education in the productive use of leisure, and an instructive example of "the difference between compulsory toil and spontaneous work."

¹ *The Grith Fyrd Idea*. By Professor John MacMurray and others. The Order of Woodcraft Chivalry. 1933. (1s.)

¹ *Klin. Woch.*, March 10th, 1934, p. 378.

As a practical means for dealing with the present unemployment it has attracted the attention of the Government, for the Ministry of Labour sent its parliamentary secretary to attend a recent meeting held in the House of Commons to discuss the Grith Fyrd Camps in relation to the Government's proposed training centres for the unemployed. Medical men who might like to see the camps for themselves should communicate with Mr. Guy Keeling, Grith Fyrd Camps, Toynbee Hall, London, E.1.

HUMANE DESTRUCTION OF ANIMALS

We have received a pamphlet from the Animal Defence Society entitled "Humane and Inhumane Methods of Destroying Animals." It is a verbatim report of a conference held last June to discuss methods of destroying dogs and cats, together with an introduction by Lieut.-Colonel Wakefield Rainey, M.R.C.V.S., and a number of letters and documents pertaining to the subject under consideration. Colonel Rainey, in his introduction, reviews impartially and scientifically, as far as the available evidence goes, the information already available. He finds that chloroform, as at present used in unskilled hands for the destruction of dogs, should be abandoned, although in skilled hands, when an adequate degree of pre-narcosis has been secured by morphine or some other drug, it is quite satisfactory. This appears to apply equally well to carbon monoxide poisoning in the form of coal gas; he is definitely opposed to the use of motor-car exhaust fumes. Shooting is an excellent method of killing, but has obvious practical difficulties in ordinary circumstances. He pins his faith to high-voltage electrocution—a method already in use in some of the large American cities, such as Detroit, with good results. (This, by the way, appears to be unknown to the conference.) He believes that low-voltage stunning with alternating current may be developed as a satisfactory method of pre-narcosis in dogs, to be followed by the intrathoracic administration of some quickly lethal agent such as prussic acid. A good narcotic for cats is nembatal, but its results are inconstant in dogs in economically practicable dosage. We would take this opportunity of welcoming this inquiry by the Animal Defence Society. Many of the methods used by humanitarian societies for the killing of unwanted animals are far from being above suspicion, and an impartial and scientific investigation into euthanasia is most opportune. While many of the speeches indicated that the approach to this in a sane, well-balanced manner would be welcomed by most of these societies, the remarks made by several of those contributing to the discussion showed that great care would have to be exercised to prevent prejudice from wrecking the good efforts of the society. Undoubtedly there is a large amount of unnecessary suffering in the destruction of animals, and we can say categorically that the medical and veterinary professions are as anxious as any other section of the community to relieve and prevent suffering in animals. Deliberate cruelty is, however, the least important of all the problems which confront the humanitarian societies. Suffering from disease, from ignorance, from

the employment of quacks, from thoughtlessness, and from mistaken efforts at kindness, are all infinitely more important, in the British countries at least, and we have no doubt that the solution to many of the problems could be found by methods of education and by co-operation with the healing professions, rather than by the erection of imaginary windmills at which to tilt. A number of bodies are already following the better course, notably the University of London Animal Welfare Society, the R.S.P.C.A., and the S.S.P.C.A., but some are not. To those whose vision has been obscured by anti-vivisection fanaticism, we suggest that an unprejudiced inquiry, on behalf of their members, would show that most of the abuses they attack have never existed, and that far more urgent and important factors, causing an infinite amount of suffering, remain unnoticed and in great need of remedy. Since the report of the discussion came into our hands we learn from Colonel Rainey that a satisfactory means of destruction by electricity, invented by a veterinary surgeon, and known as the "euthanator," is on sale for 7½ guineas at 20, High Street, Bath.

DAWSON WILLIAMS MEMORIAL PRIZE

The Dawson Williams Memorial Fund was established by voluntary subscription in 1928 to commemorate the late Editor of the *British Medical Journal*. Its object is the award of a prize every two years, or at longer intervals, in recognition of work done in connexion with paediatrics. The Fund is administered by the following trustees: The presidents (for the time being) of the Royal College of Physicians of London, the Royal College of Surgeons of England, the British Medical Association, the Royal Society of Medicine and the Section for Disease in Children of the Royal Society of Medicine, and the Editor of the *British Medical Journal*. There have been two previous awards of the prize—namely, in 1930 to Dr. F. J. Poynton, for his work on behalf of rheumatic children, particularly with regard to the establishment of special "rheumatic centres"; and in 1932 to the late Sir Robert Jones, for his work in connexion with the paediatric side of orthopaedics. The trustees have decided to make the third award this year to Dr. G. F. Still, in recognition of his work for sick children, and with the consent of the Council of the British Medical Association the prize (a certificate and cheque for fifty guineas) will be presented by the President of the Association on the occasion of his Presidential Address at Bournemouth on Tuesday, July 24th, 1934.

The fifteenth Maudsley Lecture before the Royal Medico-Psychological Association will be delivered by Lord Macmillan, on "The Professional Mind," at 26, Portland Place, W., on Thursday, May 17th, at 3 p.m. Admission without ticket.

We regret to announce the death, on April 21st, at the age of 66, of Mr. F. N. G. Starr, emeritus professor of clinical surgery in the University of Toronto. Professor Starr was vice-president of the Section of Surgery when the British Medical Association met in London in 1910, and in 1925 he was elected a Vice-President of the Association.

LEAD IN THE HUMAN BODY

A REVIEW OF THE SITUATION

The substance of the human body, though founded chemically on an organic basis, includes in its make-up certain metals which are essential to life. Such are calcium, sodium, and magnesium, and in lesser amounts iron and copper, together with manganese and arsenic and possibly zinc and tin. A place in the list, without in the meantime any claim to physiological significance, must be accorded also to lead. That this base metal, which is held accountable as a cumulative poison to man, should be commonly present in his tissues is not indeed a new conception, since it was announced by Devergie as long ago as 1838, but the introduction of new analytical methods has lent the question a fresh interest which may result in some revision of current views and standards. Mention was made in a recent issue¹ of a report by the Water Pollution Research Board which points out the existence at the present time of much diversity of opinion in matters pertaining to lead.

LEAD IN FOOD

Excepting in industry, where the outstanding lead hazard is from fume and dust, lead when it enters the body of man does so almost without exception in his food and drink. In this country it is frequently carried by water which has passed through leaden pipes, or it may be derived on occasion from the glass of bottles or the metal parts of soda-water siphons. Its concentration in food has been studied in the United States by R. A. Kehoe² and his colleagues, who, working at Cincinnati by modern methods, found in beans which they examined 0.31 milligram of lead per kilo, in meat 0.63, in apples 0.3, in cherries 0.77, and in sausages 1.6. The occurrence of the metal in meat is ascribed to the fondness of stock for licking new-painted surfaces, or to the flooding of pastures by streams conveying waste water from lead mines. Game, too, may be charged with lead, and a curious instance is quoted of the wholesale poisoning of wild duck through swallowing spent lead shot embedded in the mud about marshes. The presence of lead in grape juice is the result of the spraying of grapes with lead arsenate as an insecticide. Fruit in general, owing to the use of these sprays, was the most heavily lead-impregnated of the foods examined. Nourished on such fare the individual American, according to Kehoe and his colleagues, ingests from 1/5 to 1/3 milligram of lead per day, and excretes approximately the same quantity at the rate of 0.02 to 0.08 mg. per litre of urine and 0.03 to 0.1 mg. per gram ash of faeces.

AN INVESTIGATION IN MEXICO

It may be of interest to compare these figures, which relate to a highly organized community, with the results of another investigation, by the same observers, into the lead experience of a primitive folk living to a great extent beyond the reach of civilization. These simple people were the inhabitants of two pueblos on the Mexican plateau. They dwelt in adobe huts without furniture or metal fittings. They drank water or pulque. Their food included beef, fish, wheat, corn, beans, peas, and other vegetables, all native products. Possessing no firearms, they never handled lead shot. Their only metal implements were machetes and sickles, presumably steel or iron. Their food utensils were of wood or earthenware. Of the latter some were lead-glazed. As there were no deposits of lead ore in the neighbourhood these glazes

appeared to be the sole contact of the people with lead. It is therefore rather surprising that in all the foods above mentioned traces of lead were found. High figures were 0.4 mg. per kilo for dried wheat and beans, and 4.15 mg. for atole—a barley and corn gruel—due in all probability to the lead-glazed containers. The mean quantity of lead ingested per person was approximately 1/10 mg. per day, and the mean rates of excretion 0.01 mg. daily per litre of urine and 0.03 mg. daily per gram ash of faeces. Thus the pueblo dwellers, although their figures work out in general at lower rates than those of Cincinnati residents as quoted above, were nevertheless ingesting, absorbing, and excreting lead in measurable quantities.

Kehoe and his colleagues therefore conclude that lead is a natural constituent of the soil and vegetation of the two pueblos and of other primitive places on the Mexican plateau, and, further, they do not doubt that the presence of lead in human tissues is an inevitable consequence of life on a lead-bearing planet. This last seems a wider generalization than the Mexican figures entirely warrant. These are reasons why the soil of Mexico may be richer in lead than that of some other countries, so that Mexican experience may not represent normal or basal rates for mankind as regards the ingestion, absorption, or excretion of the metal. Studies of the position in other lands would throw useful light on an interesting question.

ARE LONG-CONTINUED SMALL DOSES HARMFUL?

The difference between the amounts of lead ingested by the Mexicans and the Americans is primarily due to the difference in the lead content of their respective diets. Kehoe and his colleagues do not claim that their results have the value of a new phenomenon or raise a new hygienic problem. Comparable quantities of lead to those which they record have, they think, occurred in food for a long time. While their researches do not disclose whether the continual absorption of minute amounts of lead has any influence on the general health, their work has made it abundantly plain that under the conditions of observation—that is to say, with an ingestion of lead up to 1/3 mg. per day—accumulation does not occur, a state of equilibrium having been reached where excretion keeps pace with absorption. This finding should serve to dissipate the belief, nebulously held by many, that minimal doses of lead, if long enough continued, are pretty sure in the end to produce lead poisoning.

DIAGNOSTIC SIGNIFICANCE OF LEAD IN EXCRETIONS

Applying their results in the domain of food to the industrial field, the observers expose another error—namely, the view that the detection of lead in the urine and faeces of workers exposed to lead hazard is valuable diagnostic evidence of lead intoxication. In any area where quantities of lead are apt, as in Cincinnati, to be ingested with food, the mere presence of the metal in the excreta of a worker can possess no diagnostic significance. Kehoe and his colleagues give as a general indication that if the average lead hazard of a trade results in a mean daily faecal output of lead in excess of 1.1 mg., and in a mean urinary excretion of lead in excess of 0.21 mg. per litre, cases of lead poisoning may be expected to occur among the workers concerned, but as regards the individual case they say that diagnosis must continue to rest largely on the discovery and interpretation of the clinical evidence. An abnormally high rate of lead excretion may serve as a guide to the severity of the lead hazard: it does not constitute proof of lead poisoning. Indeed, no definite rate of lead excretion can be held to presuppose the existence of symptoms or to explain the symptoms actually presented by the patient. Even abnormal lead absorption should not be rated unduly

¹ *British Medical Journal*, March 31st, 1934.
² *Journ. Indust. Hyg.*, September, 1933.

high, since lead absorption is not synonymous with lead intoxication.

These views are sustained by the findings of Professor L. S. P. Davidson³ and his co-workers in their report on water-borne lead poisoning in the North-East of Scotland. Lead excretion corresponded with hazard—that is to say, was higher among consumers of the heavily impregnated waters—but no significant relationship appeared to exist between a highly impregnated water and either a high urinary excretion of lead or the occurrence of plumbism.

The work done by Kehoe and his colleagues seems to merit the attentive consideration of medical officers of health, certifying factory surgeons, medical practitioners, and all who have to do with the prevention, diagnosis, or treatment of lead poisoning. That there is need in some quarters for greater clearness on the subject is suggested by data contained in a report by F. L. Hoffman,⁴ which exhibit for Germany a remarkable difference between the numbers of reported and compensated cases of plumbism, and also by a pronouncement recently issued by the white-lead manufacturers of Europe, who, in stating the case against prohibition of the use of their commodity, present evidence strongly pointing to the insufficiency of the average diagnosis of lead poisoning.

THE MILK SUPPLY

PURITY AND SAFETY

The Minister of Health, Sir HILTON YOUNG, received a deputation on April 18th from the People's League of Health. The deputation was introduced by Dr. C. O. HAWTHORNE, Chairman of the Council of the League, who said that the League had made a special study of the question of milk, and was in sympathy with the campaign to encourage its increased consumption. At the same time it was very fully aware of the risks involved and believed that these risks were avoidable, and should be avoided.

MEDICAL ARGUMENTS FOR PASTEURIZATION

LORD MOYNIHAN said that milk was almost a perfect food. The amount of milk consumed in this country was much less than in many other countries, and there would undoubtedly be great advantages in increasing its consumption here. Unfortunately, the existing milk supply was not safe. From 9 to 15 per cent. of samples of milk examined were contaminated with tubercle bacilli. Even "Certified" milk had been found to contain tubercle. Contaminated milk was also responsible for the spread of other diseases, such as undulant fever and scarlet fever. The chief desire of the People's League of Health was to secure the eradication of tubercle from cattle and to obtain a supply of clean and safe milk. But the cleaning up of herds was a long process, and for the present all milk other than "Certified" milk and "Grade A (tuberculin-tested)" milk should be pasteurized.

Professor S. LYLE CUMMINGS said that he did not believe there was any conflict between the interests of farmers and the views of doctors. All desired to get rid of tubercle in man and in cattle. Much tuberculosis and, indeed, a large proportion of tuberculous meningitis was due to milk-borne infection. It would be advantageous if the tuberculin-testing of cattle could be carried out free of charge, and if the several existing grades of milk could be replaced by one single grade of tuberculin-tested milk. Dr. R. C. JEWESBURY said that the medical profession was no longer justified in advising the use of raw milk for children. It was important that pasteurization should be carefully controlled.

Sir JOHN ROBERTSON agreed that a supply of milk pasteurized under control was much to be desired. In Birmingham, where he was formerly medical officer of health, there had been a much longer experience of the benefit of sterilized

milk than in any other town in the country. His knowledge of this experience had convinced him that the use of this milk had had no harmful results, and had played a large part in preventing milk-borne diseases. Sir PENORILL VARRIER-JONES said that all milk at the Papworth Village Settlement was heat-treated, with the result that no Papworth-born child had shown any clinical signs of tuberculosis, nor had a Papworth child died of any disease. Dame LOUISE McILROY spoke of the needs of infants who could not be breast-fed. It was most desirable to have a supply of pure milk available for working-class mothers. She also drew attention to certain unhygienic methods which she had noticed in milk distribution in the streets of London.

Dr. WILLIAM HUNTER, who represented the Royal College of Physicians, said that the College was in full sympathy with the object of the deputation, and its President, Lord Dawson, would have been present had he been in England. Mr. C. H. FAGGE, representing the Royal College of Surgeons, said that this College was also in full sympathy with the deputation.

Miss OLGA NETHERSOLE, the founder and honorary organizer of the League, put in letters from Sir Farquhar Buzzard, who wrote that "If the surplus milk of the country is to be distributed amongst children under the authority of the Government . . . it can only be done under such conditions as will safeguard the children from preventable and serious diseases"; from Professor Langdon Brown, who wrote that "No medical man of an experience can fail to recognize the dangers of milk-borne disease"; and from Lord Horder, Sir John Rose Bradford, Sir Robert Philip, and Sir Francis Fremantle, sympathizing with the objects of the deputation.

MINISTER'S REPLY TO DEPUTATION

Sir HILTON YOUNG said that he was deeply grateful to the People's League of Health for the statements made to him by its influential deputation. He much regretted that Dr. Walter Elliot had been prevented by illness from joining him in the reception of the deputation, though he was glad to be able to say that a representative of the Ministry of Agriculture (Mr. H. E. Dale) was present. He could assure the deputation that it was preaching to the converted. The safety of the milk supply was of pre-eminent importance, because of its direct effect upon child life. It was of great advantage to the campaign which was being undertaken for the improvement of the milk supply that milk producers were now organized, and the deputation could be assured that the Milk Marketing Board was fully conscious of its responsibilities. He agreed with Lord Moynihan that it was necessary to proceed simultaneously along two lines of advance. In the first place, all that was possible must be done to remove infection from herds, and in the second place steps must be taken for the protection of milk. As the deputation would be aware, the Government was proposing to provide from public funds a sum not exceeding £750,000, spread over the next four years, in aid of a campaign for securing a purer milk supply. No final decision had yet been taken how best that money could be spent, and before reaching a decision the Government was awaiting the report of the Cattle Diseases Committee of the Economic Advisory Council, under the chairmanship of Sir F. Gowland Hopkins, which, it was understood, was just concluding its labours. The importance of educating the public in regard to the milk supply was very great, and in this task especially the People's League of Health, which was so influentially supported, could be of the greatest assistance.

Two Chinese workers, Drs. Wong and Chang, have recently published a series of papers concerning the action of acetylcholine on the uterus (*Chinese Journ. Physiol.*, 1933, xlvii, 162 and 987). The authors first showed that in cases where uterine contractions were strong and active the placentas contained relatively large amounts of acetylcholine. In a later paper they have studied the action of acetylcholine on animal uteri and also on the human uterus. They observed that the drug produced an oxytocic action much weaker than that of pituitrin, but that it had the advantage of increasing uterine activity without producing spasm. They have found the drug to be of value in the management of labour.

EPIDEMIC NERVOUS DISEASES IN 1932-3

The January-February issue of the *Epidemiological Report* of the Health Section of the League of Nations contains a survey of the incidence and mortality of cerebro-spinal meningitis, encephalitis lethargica, and poliomyelitis throughout the world in 1932-3.

As regards cerebro-spinal meningitis, the most important outbreak in Africa was that which occurred in Lower Egypt in 1932. It had begun in November, 1931, and reached its climax with almost 1,000 cases, and 500 deaths per fortnight, at the beginning of the following March, after which it rapidly declined. A recrudescence, however, took place in November, 1932, and lasted till March, 1933, after which there was a slow regression. The total number of cases in Egypt in 1933 showed a two-thirds reduction in the prevalence of the disease as compared with 1932. An epidemic of meningitis also occurred in the Anglo-Egyptian Sudan in 1932-3, but the outbreak of 1933 was of much shorter duration than that of 1932. In the United States the incidence of cerebro-spinal meningitis fell from 5,534 in 1931 to approximately 3,000 in 1932 and 1933. In Asia the pandemic which occurred in the Far Eastern ports, especially those of China, in the spring of 1932 showed a further increase in 1933. In British India cerebro-spinal meningitis is a comparatively rare disease with the exception of Calcutta, where well over a hundred deaths took place in 1932 and 1933. In Turkey, owing to a campaign of antimeningococcus vaccination in November, 1932, a considerable decline took place in the incidence in 1933, only four cases having been noted among approximately 74,000 vaccinated. In Japan, where diseases of the central nervous system are particularly frequent, encephalitis lethargica and cerebro-spinal fever are often confused, and no figures are given of the incidence of meningitis in the last two years. In Europe the highest death rate was found in Great Britain, although the disease became stationary in 1932 and even showed a slight decline in 1933. Except in Germany, where the death rate rose from 0.3 to 0.9 per 100,000, the disease was everywhere on the decrease in 1932 and 1933.

As regards encephalitis lethargica, apart from the United States, where an epidemic occurred in Missouri and Illinois from July to October, 1933, similar to the sudden outbreak in Japan in 1924, there was a decrease in almost all the countries for which statistics were available. Lastly, as regards poliomyelitis, the most important focus in 1932 was Germany, where the disease was prevalent in Upper Bavaria, Oldenburg, Hanover, Pomerania, and Silesia. In 1933 the incidence declined everywhere, except in Pomerania. In England the morbidity rate, 1 per 100,000 in 1931, rose to 1.8 in 1932 and 1.9 in 1933. In Denmark epidemics broke out in July, 1933, and in Sweden and in Hungary in 1932. In North America endemic poliomyelitis in Canada persisted in 1932, but showed a great improvement in 1933. In the United States the number of cases fell from more than 16,000 in 1931 to less than 4,000 in 1932, but there was a certain increase in some States in 1933. In Australia epidemics occurred in Queensland and New South Wales during the first six months of 1932, but the disease became less prevalent in 1933.

The report of the St. John Ophthalmic Hospital, Jerusalem, for 1933 shows that 1,179 in-patients were treated, that new out-patients totalled 20,535, total attendances 89,895, and operations 3,630. The Government having increased the local clinics by three during 1933, the Order of St. John is now responsible for the oversight and inspection of ten Government ophthalmic clinics in Palestine. This has necessitated an additional member of the hospital staff, which now numbers four. The hospital suffered severely in its work by the terrible shortage of water experienced during practically the whole of the year. The Order was called on to feed the suffering and destitute in its annexe last summer, and gave a total of 1,615 meals in addition to the necessary medical treatment. It is intended to open a school in Jerusalem under the supervision of the warden of the hospital, Dr. J. C. Strathearn, for the training in hygiene, home nursing, sanitation, and first aid of young Arab girls.

England and Wales

University of Birmingham: A Department of Industrial Hygiene and Medicine

For several years past there has been growing up a demand for the establishment in this country of a university department which would undertake research in the application of medicine to industry, and which could offer a special training to doctors who are whole- or part-time medical officers to industrial organizations or who wish to qualify for such posts. For various reasons, but largely because of the great variety of manufactures carried on in the Midlands, it has been considered that Birmingham would be an ideal centre from which this work could be directed. The research work contemplated would inquire into such questions as the deleterious action on workpeople of the materials they work with, and particularly of various chemical substances and their emanations, and the methods whereby diseases are contracted by workers as a result of some industrial process; and, as a corollary, what methods of prevention can be devised. It is further anticipated that doctors would be trained to advise employers as to methods by which the number of certain types of accidents might be reduced; as to the most effective way of dealing with them when they arise; as to the selection of employees for various kinds of work so as to ensure that they are physically adapted for it; and as to improving the hygiene of factories and the general health of the workers. It is probable that the university will arrange to grant a diploma to those who complete the course successfully. Inquiries have been made as to how far such a department would be utilized by employers, and, although only a small number of firms have been tentatively approached, it is clear from their replies not only that the demand exists, but that the services of such a department are likely to be of increasing value to industry. This is also the opinion of such representatives of the Home Office as have been consulted. The University of Birmingham has therefore decided to institute a Department of Industrial Hygiene and Medicine, and arrangements are being made with a view to its opening on October 1st, 1934.

Cost of London Municipal Hospitals

The estimates of expenditure on hospital and public health provision for the financial year 1934-5 were placed before the London County Council at its meeting on April 24th. Some figures given for the general hospitals maintenance expenditure in our issue of March 31st were based only upon a two months' provision. The figures for the year are as follows:

	£
General hospitals	2,814,515
Infectious diseases hospitals	934,865
Sanatoria... ..	191,040
Children's hospitals	325,660
Pathological laboratories	49,500
District medical service	38,800
Ambulance service	169,590
Diagnosis and treatment, venereal diseases	115,600
Maternity and child welfare	31,675
Midwives Acts	5,475
Other items, including maintenance in hospitals other than those provided by the Council, staff expenses, sanitary officers, and public vaccinators	498,770
	£5,175,450

The estimates show an increase of £35,030 on the original estimates for the year 1933-4. In addition, on capital account, an expenditure of £230,900 on general

hospitals, and of £60,000 on other hospitals is forecast. This is due to the need for extensions and reconditioning works.

New Coventry Isolation Hospital

On April 19th the Mayor of Coventry opened the new City Isolation Hospital, which has been erected on a site of sixteen acres at Whitley in Warwickshire, at a cost of £115,000. The previously occupied buildings are being handed over to the governors of the Coventry and Warwickshire Hospital on May 1st. Further extension has been provided for by the securing of an additional ten acres of adjoining land. The new buildings comprise an administrative block, three ward blocks for acute cases, two ward blocks for convalescent cases, one cubicle ward block, a power block, a house for the resident medical officer, two staff cottages, and an entrance lodge. The various blocks are in terrace formation. Each of the three for acute cases contains twenty-eight beds placed in two main wards and two single-bedded wards. Simultaneous observation of the four wards is rendered possible from the central duty room by an ingenious arrangement. Each of the two convalescent blocks contains twenty-six beds, which are included in two main wards. These blocks possess deep verandas in front, and day rooms placed centrally at the first-floor level. All the blocks are of the one-story type. The cubicle block contains twelve beds, each of which is placed in a separate cubicle. From the central duty room observation of the twelve cubicles—six on each side—is rendered possible by means of glass panels in the dividing walls. This block has also a spacious veranda. The operating theatre unit is conveniently placed at one end of the cubicle block. The administrative block is situated centrally on the site, and is designed to be adaptable to any future extension of the whole institution. Part of it is arranged as a nurses' home, with thirty-six bedrooms and a spacious common room. The kitchen part is essentially modern, with electric ovens and electrically driven machines for various culinary processes. The meals will be delivered from this central kitchen to the various wards in trolleys fitted with electrically heated containers. The power block contains the boiler-house, water-softening plant, an engineer's workshop, the hospital laundry, a disinfecting plant, a weighbridge, and garages for ambulances. The mortuary is attached to this block. All the buildings are centrally heated from the boiler-house; a system of panel heating is installed in the five large ward blocks, and in the wards there is a shaded wall light at the head of each bed. Complete intercommunication between the various hospital buildings is secured by a system of internal telephones. The new hospital is just under two miles from the city centre, and the separate small-pox institution is rather less than half a mile away; this enables the staff of the main hospital to exercise any required supervision. In its general planning and up-to-date equipping the isolation hospital is held to be one of the finest in the country.

Healthy Offices for Clerical Workers

A meeting of London members of the Association of Women Clerks and Secretaries was held on April 17th to discuss the problem of office accommodation in view of the failure of the Offices Regulation Bill to obtain a second reading in the House of Commons. Dr. W. J. O'Donovan, M.P., suggested that it was not only necessary to educate Members of Parliament on this question, it was also necessary to educate those older clerical workers who had become hardened to bad conditions through long experience. Younger workers, with more modern ideas of hygiene, would not accept the conditions which prevailed. Thousands of houses which had been built as dwelling

places were converted for use as offices, and were quite unsuitable for that purpose. The problem was not only one of old buildings, but the use of underground rooms in new modern buildings. Mr. Arthur Greenwood, speaking as an ex-Minister of Health, said that a great deal of "tripe" had been talked during the debate on the Bill about the protection offered by the Public Health Act. All administrators knew that these Acts were quite inadequate to deal with this problem of bad offices. Factory workers had secured adequate protection, but office workers in the past had been too respectable to agitate. They must strengthen their organizations to enable the fight for better conditions to go on. A resolution, deploring the existence of unhealthy offices and urging adequate legislation to secure a minimum health standard for office workers, was carried unanimously.

Scotland

Milk Consumption in Scotland

A report has recently been issued by the Department of Health for Scotland embodying the results of an inquiry by Drs. Gerald Leighton and Peter L. McKinlay into the average amount of liquid milk consumed in Scottish households. There would appear to be general agreement that the amount of milk used in Great Britain is smaller than in any other country. The report points out that no national data are available for Great Britain, but that information has been derived from four main sources: co-operative societies, private retailers, health visitors and nurses, and education authorities. The figures cover every kind of district and community—urban, rural, industrial, and agricultural. It was found that consumption varied greatly in different localities, and that the figures for the large burghs were generally lower than those for county districts. In individual burghs the amount varied from 0.27 pint daily per person in Hamilton to 0.7 pint in Perth, while in counties it varied from 0.3 pint in Lanarkshire to 1.03 pints in Aberdeenshire. The general average for large burghs was 0.4 pint, and in counties exclusive of large burghs 0.55 pint. In Scotland as a whole the amount of milk consumed was found to be 0.479 pint per person per day. It is emphasized that in making an inquiry of this nature several fallacies have to be avoided. The amount of milk entering some particular city is not necessarily consumed by the inhabitants; the city may have a margarine factory, while large quantities of milk may also be used by biscuit factories, chocolate factories, ships, animals, etc. It was found that in nearly all towns the largest distributors were the co-operative societies. For the purposes of this report, eighty-four of these societies scattered over Scotland supplied details of milk distribution. Health visitors and nurses also ascertained from each house visited in the ordinary course of their work the amount of milk taken daily for the number of inhabitants; in this way 15,187 households, containing 80,242 persons, were recorded over a period of some ten months. Returns were also obtained through the Scottish Education Department by ascertaining from senior scholars in schools all over the country the amount of milk taken daily in their families and the number of persons in the house. These returns covered 66,149 families containing 393,726 persons. An appendix to the report states that the total milk produced in Scotland in 1925 was 171,000,000 gallons yielded by 398,000 cows, but that this does not represent the milk used in liquid form. Statistics from the United States indicate an average daily consumption per person of about 1.47 pints of milk and cream, although this is an over-statement

of the amount used as fluid milk, which was slightly more than one pint per day in 1926. The pamphlet can be obtained from H.M. Stationery Office, 120, George Street, Edinburgh (price 9d.).

Two Edinburgh Maternity Hospitals

The joint annual report for the year ending November 30th, 1933, of the Edinburgh Hospital and Dispensary for Women and Children (Bruntsfield Hospital) and the Elsie Inglis Memorial Maternity Hospital (The Hospice) covers a period of steady activity in spite of considerable financial difficulty. The total number of new in-patients at the Bruntsfield Hospital was 809, and there were 1,115 new admissions at the Elsie Inglis Hospital. At the first-named the electrical and massage department was in increased demand, and the diagnostic work of the x-ray room was intensified, while the out-patient department attendances rose by over 2,000. All patients at this institution, except those in the private wards, where a fixed charge is made, are asked to contribute according to their means towards the cost of their treatment; for those unable to do even this there are free beds, which are in continual occupation. In connexion with the Elsie Inglis Hospital it is mentioned that in the 1,101 cases delivered there between December 1st, 1932, and November 30th, 1933, there has been no instance of puerperal fever due to the specific organism. Plans are nearing completion for building a permanent ante-natal and out-patient department, where further accommodation has long been needed; there are always between five and six hundred patients on the lists. The two institutions, with their total of 116 beds, apart from the six cots at the Bruntsfield Hospital, now provide a complete unit for the treatment of women in every branch of medical science. In the last two years, with the addition of an ear, nose, and throat specialist, there has been brought together a complete specialist staff of fully qualified women, which admits of valuable team work. In the medical part of the combined report reference is made to the gratifying results of the special efforts made, as regards bacteriological research and control, to eliminate infection by the *Streptococcus haemolyticus*. It is concluded that by the methods adopted the risk of contagion by this organism can be eliminated. A separate bulletin has been issued showing the results of the three years' investigation. The number of cases of malignant disease treated by radium in 1933 was less than those in the two preceding years, and it is pointed out that further education of the public is still necessary, since too many advanced cases are being encountered. A new departure in the year under review was the organization of a fortnight's intensive post-graduate course by the two hospitals in gynaecology, obstetrics, and allied subjects. It is now proposed to hold this course for women doctors twice each year in future, and to include lectures, clinics, and pathological demonstrations.

Glasgow Ear, Nose, and Throat Hospital

At the annual meeting of the Glasgow Ear, Nose, and Throat Hospital, held on April 19th, Lord Provost A. B. Swan, who presided, said the hospital was doing a great deal to raise the standard of health and efficiency in Glasgow and the West of Scotland, and that he hoped the opportunity would soon be taken to extend the building. The report showed that 15,066 patients had received treatment, including 2,415 in-patients, a marked increase on the figures for the previous year, which were 13,518 and 1,956 respectively. Subscriptions had amounted to £6,834 as compared with £6,699 in 1932, and the total income had been £8,198, while the expenditure had been £8,355.

Simpson Memorial Maternity Hospital

The report presented to the annual meeting of the Edinburgh Royal Maternity and Simpson Memorial Hospital showed that the number of cases treated by the hospital in the past year had been 3,450, while patients attending the out-patient clinics had numbered 15,832. An arrangement had been effected with the Edinburgh Corporation whereby emergency accommodation was provided in the Western General Municipal Hospital; this arrangement had relieved congestion in the ante-natal department. Patients admitted to the hospital or attended in their own homes by the hospital's nurses had been equivalent to 45.4 per cent. of the total births in Edinburgh during 1933. During the year 11,070 visits had been paid by doctors and nurses in connexion with the outdoor department; this was equivalent to 11.6 visits per case. It was announced at the meeting that the plans of the new hospital, to be taken over by the management of the Royal Infirmary, had now been approved, and that the construction of the Simpson Memorial Maternity Pavilion, which would replace the present Maternity Hospital, would be begun immediately. It was expected that the new hospital would be ready for the reception of patients in the spring of 1937, and May 15th in that year had been fixed as the date on which the management of the Maternity Hospital would be handed over to the Royal Infirmary. The deficit of £3,146 on the working of the hospital during the year had been withdrawn from the reserve fund, and a very urgent appeal was made for a steady subscription income of at least £4,500 per annum during the next three years.

India

Blindness in India

An appalling prevalence of blindness in India is revealed by figures published by the National Institute for the Blind (Great Portland Street, London). These give an estimate of 1,500,000 Indians totally blind and 4,500,000 with "gravely affected" sight. Sir Michael O'Dwyer, a member of the council of the Institute, declares that a large proportion of the latter four and a half millions are so bad that they would be certifiable as blind if they lived in this country. Much of the trouble is preventable, and it is with a view to checking the trouble in its earlier stages that the Institute has made an emergency grant to finance a propaganda scheme. The money will be used by the Indian Junior Red Cross Society in distributing pamphlets in the vernacular and in organizing lectures to teachers. A memorial prepared by leading authorities was recently presented to the Government of India urging official action, but, though the Government was sympathetic, nothing could be done "owing to the present financial stringency."

Kashmir Mission Hospital

Dr. Ernest F. Neve has published a review and summary of the work of the Kashmir Mission Hospital during the last half-century in which this institution has been presided over by the late Dr. Arthur Neve and the author. It has been serving a population of about one and a half million people in Kashmir itself, and has become a centre of pilgrimage for the sick in such far distant parts as Tibet, Bombay, Calcutta, and Madras. Situated in Srinagar with a population of more than 140,000, and having won by steady persistence the support and approval of Moslems and Hindus, it also sends expeditions into the villages about two or three times a year, has been

the pioneer in leprosy work in that part of India, is now fighting hard against the growing menace of tuberculosis, and in the last fifty years has treated 825,000 new out-patients, admitted over 72,000 cases to its wards, and performed 197,522 surgical operations, the average weekly number of which at present is about seventy. In 1933 there were 23,046 new out-patients, 2,243 in-patients, 3,932 operations, and 3,000 laboratory investigations. During the last twenty years much progress has been made in co-ordinating the work of the Mission Hospital with the State medical organization, the Diamond Jubilee Hospital, the city dispensaries, and the increasing number of capable general practitioners. Of the 160 beds, 100 are maintained by individual supporters or corporate associations. About one-third of the patients are women and children, many of the latter suffering from the consequences of neglect and starvation. Osteomalacia is a common characteristic of the maternity work; it is attributed to some special form of toxic infection originating from vitamin deficiency and insufficient exposure to sunshine. In the district work of the hospital infestation by ascariades figures largely, as also do diseases of the alimentary system. Cataract extraction is frequent, but the commonest cause of blindness in Kashmir is entropion and trichiasis. Bone diseases are unusually common.

Rural Sanitation in Agra and Oudh

The continued financial depression led to still further curtailment of the public health activities of the United Provinces of Agra and Oudh in 1932, and it was fortunate that climatic and other conditions were not such as favour epidemics on a grave scale. The labour gangs, which proved so effective in promoting sanitary conditions in villages, had to be abolished. This greatly hampered the work of the small local health staffs, and medical officers had to rely on their powers of persuasion to induce the villagers to take an active interest in their sanitary arrangements. In this respect the "village aid scheme" played an important part. It comprised three distinct activities. At least two of the inhabitants in each village receive special training in elementary sanitation and first aid. This enables them to guide the villagers in ordinary needs and difficulties, and many instances are on record of snake bite, scorpion bite, and drowning having been effectively treated by these "first-aiders," while disinfection in suspected cholera has been adequately dealt with. Secondly, there have been established, generally in charge of village school teachers, dispensaries stocked with a few simple remedies. These create a demand for more skilled medical treatment, but their financing has proved difficult owing to the lack of support by most of the district boards. Thirdly, efforts have continued to ensure the storage of manure and refuse outside the inhabited sites, preferably in pits, and to promote the construction of soakage pits. The total number of village aid dispensaries rose from 2,082 at the end of 1931 to 2,316 at the end of 1932, and the number of trained villagers from 58,496 to 74,933. In the Gorakhpur district there are resident public health officials who can supervise the disinfection of wells in the villages in their areas, distribute anti-cholera medicaments and quinine, deal with vaccination and the collection of health statistics, enforce the local by-laws, train village dais, and give instruction on health matters. In the year covered by this report Lieut.-Colonel W. A. Mearns, I.M.S., Director of Public Health for Agra and Oudh, was able to trace the great advantages gained by this system. The number of those vaccinated increased very considerably, there was a great reduction in deaths from cholera, the vital statistics became much more accurate, and the villages were better cleaned. Inducements are also offered by

the district board of Gorakhpur to the dais to improve the standard of their efficiency. Colonel Mearns remarks that this scheme is an experiment in public health, based on experience gained in Travancore, Ceylon, and other parts of the world. The underlying idea is to apply a more detailed public health organization to a limited area in order to demonstrate what intensive health measures can achieve, and to create a demand for better sanitation.

Ireland

Conditions of Service for Poor Law Medical Officers in the Free State

A meeting of representatives of the Poor Law medical officers in the Irish Free State was held on April 17th in the Royal College of Surgeons, Dublin, with Dr. Conor Maguire in the chair. The meeting decided that the General Council of Medical Associations in the Free State, which is the executive of the Irish Medical Committee, should be requested:

(1) To appoint six Poor-Law medical officers to investigate the very unsatisfactory conditions of service of Poor Law medical officers in the Irish Free State as compared with general medical practitioners and Poor Law medical officers in Great Britain and Northern Ireland, the proposed committee to make a report embodying recommendations for consideration as early as possible by a meeting of Poor Law medical officers to be held in Dublin; (2) to consider the question of the tenure and purchase of dispensary houses by the occupying medical officials and their dependants, the reduced remuneration for administration of anaesthetics in county and district hospitals under the health boards, and a recent order issued to district medical officers of health in County Wexford directing them to notify immediately maternity cases in which the temperature is raised for twenty-four hours.

A resolution was passed unanimously approving of the affiliation of the British and Irish Medical Associations.

The Benn Hospital, Belfast

The report presented to the recent annual meeting of the Benn Ulster Eye, Ear, and Throat Hospital showed that the number of patients treated during the year was 4,448 and the total attendances of both old and new cases were 15,994. Patients admitted to the wards for intern treatment from the city of Belfast and the following counties numbered 871: Belfast 536, Antrim 104, Down 97, Tyrone 38, Londonderry 27, Armagh 26, Fermanagh 22, Monaghan 18, Kildare 2, and Donegal 1. There was an increase of 787 in the total attendances. During the year, through the interest of Sir Robert Kennedy, the hospital received a grant of £150 from the Ulster V.A.D. Committee of the British Red Cross Society and the Order of St. John of Jerusalem to purchase a fumigator for mattresses and dressings. The report expressed thanks also to the committee of the County Antrim Branch of the British Red Cross Society and the Order of St. John of Jerusalem for the generous grant of £50 for the purchase of a gas-and-oxygen apparatus, and to Mrs. Malcolm Gordon and the members of the Linen League. The medical and surgical report stated that the total number of eye patients attending was 2,203, and of ear, nose, and throat patients 2,245. Operations to remove cataract from the eyes numbered thirty, mastoid (ear) operations fifty-two, dissection of tonsils 136, and removal of tonsils and adenoids (chiefly in children) 310; the total number of operations of all kinds was 1,222. The hospital has now an excellent equipment for removal of metal and other foreign bodies from the eyes by electro-magnets, etc.

Reports of Societies

FAILURES OF GASTRIC SURGERY

At a meeting of the Medical Society of London on April 23rd, with Sir JOHN THOMSON-WALKER presiding, the subject of the discussion was "The Failures of Gastric Surgery."

CAUSES OF FAILURE AND THEIR AVOIDANCE

Dr. JOHN A. RYLE, in opening, said that he hoped it might become the custom to devote one evening in each session to a review of therapeutic limitations, errors, and failures. All true advances in therapeutics must pass through an experimental phase in which indications were sifted and technique developed. During this phase the results would be found to vary considerably in relation to individual judgement and ability, and gastric surgery was no exception to this rule. Their self-criticism should take the form, not of condemnation, but of analysis. He hoped the discussion would not degenerate into an argument for medical methods as opposed to surgical, or for one surgical method as opposed to another. There had been from time to time a tendency for the surgeon to decry the physician, and vice versa, in respect of the treatment of peptic ulceration, but this antagonistic habit of mind was unbecoming and unphilosophical.

What constituted a failure? Briefly, an operation which left the patient immediately no better, or worse, than before, or resulted in death, when the condition might have been cured or greatly palliated by medical means, must be regarded as a surgical failure. The causes of failure might be subdivided into those due to technical error or surgical inexperience, and those due to faulty selection and judgement. Faulty judgement was held to include decisions to operate in cases in which there was no sufficient justification for surgery at all, in which the medical treatment had been given no trial or no sufficient trial, or in which the patient's state of health made surgery an unwise procedure. He enumerated five complications of gastro-jejunostomy deserving the name of partial or complete failure: (1) the dumping stoma; (2) vicious cycle vomiting; (3) recurrent haemorrhage; (4) persistence of the original ulcer; and (5) anastomotic ulceration. In considering the measures necessary for the avoidance of failure, he urged first a close attention to the age, physical and mental type, general fitness, family history, occupation, habits, and economic status of the patient, and secondly the duration of the ulcer. The final decision should never be based on any rule-of-thumb method, but on a careful review of all the available evidence, general or local. Commonly the decision should require the co-operation of physician and surgeon. Every operation should be followed by an adequate period of dietetic treatment. Dr. Ryle added that he had no wish to exaggerate the frequency of failure. For every ten cases of duodenal ulcer seen in private practice he saw one case of anastomotic ulcer. But caution should not be dictated solely on account of the numerical frequency of the failures; their gravity also had to be considered. When gastric surgery failed to relieve it commonly left the patient in a worse state than before, but the same could not be said of medical treatment. The triumphs of surgery were more complete and lasting than those of medicine, but by the very nature of the risks undertaken the failures of surgery were more complete and lasting also.

OPERATIVE PROCEDURES: RISKS AND COMPLICATIONS

Mr. A. JAMES WALTON said that surgeons had to thank Dr. Ryle for the moderate and friendly way in which he had considered some of their failures. He associated himself with him in saying that the days in which a surgeon was simply required to know how to operate were long since passed; one of the surgeon's most important functions to-day was to know when to operate. The first group of errors in gastric surgery was that of diagnosis. It was a difficult matter indeed to estimate the

proportion of these cases. It was true that to-day surgeons were not called upon to operate simply because the patient had symptoms which were somewhat anomalous and had not reacted to medical treatment. In the old days it was said that medical treatment had failed, and therefore surgical treatment should be given a chance: that principle was not put forward to-day. Mr. Walton produced statistics relating to 2,343 cases which had passed through his hands. Of these, in 171 the expected surgical lesion was not found; thus the failures in diagnosis amounted to 7.2 per cent., which he thought was still much too high. The next big group comprised those which he might call operations for medical lesions. There were groups of cases in which an operation should not be carried out because the patient could be cured by medical means. One had to take into account the widespread dread of operation, which was not confined to the ignorant, but prevailed among people of the educated classes, including medical men, who understood what was going to happen to them. Very few cases now came to him in which he could say that the patient had had no opportunity of medical treatment. It was also agreed that the more unsuitable the case or the patient for operation the longer should medical treatment be tried. Again, owing to increasing knowledge of the effects, surgeons were not now so often asked to operate for visceroproposis, chronic colitis, and other similar lesions. It was necessary also to bear in mind the group of patients who died from operation. In most of the statistics given the operative mortality was not considered, but he wanted to point out that there was no operation whatever to-day which was free from danger to life. Every operation was associated with a certain risk, and one had always to balance up most carefully the risk of the operation against the risk of the condition present in the patient; and that, of course, entailed a very careful consideration of the patient's condition. They were often told that there was a certain lesion which required a certain operation. That might be useful for undergraduates, but in practice it was absolutely futile. The three conditions which were most important to consider were the age of the patient, the presence of complications, including obesity, and the experience of the surgeon. It was noteworthy that as one's experience of a certain disease increased, so did one's mortality rate rise. The explanation was that the experienced surgeon increasingly had sent to him for operation extremely bad risks, the simple cases all being done locally. But that circumstance showed how valueless were mere lists of statistics. His own operative mortality had been as follows:

	Cases	Deaths	Per cent.
Posterior gastro-enterostomy for duodenal ulcer	703	14	2.0
Posterior gastro-enterostomy for all uncomplicated lesions	816	25	2.9
Surgical resection for lesser curvature ulcers	272	12	4.4

He also gave figures of five-year cures after operation. These showed 74.2 per cent. after partial gastrectomy, 92.1 per cent. after surgical resection for lesser curvature ulcers, and 88.4 per cent. after posterior gastro-enterostomy for pyloric and duodenal ulcer.

A great deal was heard to-day about the failures of surgical operation, and there were, of course, definite failures; but he desired to stress the fact that these formed a very small percentage of the total. Among the actual failures some were due to errors of technique, of which he enumerated some gross illustrations; fortunately these were becoming rarer. He believed that post-operative haemorrhage was due to errors in technique, but it was very difficult to lay one's finger on the error, and therefore difficult to avoid it. Some cases were due to accident which could not be predicted or prevented. There were four complications upon which a good deal of stress had been laid—namely, gastro-jejunal ulceration, and recurrent ulceration, subsequent onset of carcinoma, and presence of post-operative anaemia. Gastro-jejunal ulceration was common only after posterior gastro-enterostomy for duodenal ulcer. The condition was much more common

in males, and was definitely due to hyperacidity. This complication must not be put down entirely to the fault of the surgeon. Errors of technique, such as the use of Murphy's button, might increase the incidence of gastro-jejunal ulcer, but a faultless technique would not abolish it. To his mind there could be no doubt that there was one treatment—namely, a partial gastrectomy performed sufficiently widely to reduce permanently the acidity—which would prevent the occurrence. With regard to recurrent ulceration, gastro-enterostomy was an insufficient operation for lesser curvature ulcer. In 117 of his cases in which gastro-enterostomy for gastric ulcers was done there were five cases of recurrent ulceration; in 865 cases in which this operation was done for duodenal ulcers four developed ulcers on the lesser curvature; after a partial gastrectomy in 469 cases there was no case of recurrent ulceration. There could be no question that the routine operation for duodenal ulcer should be posterior gastro-enterostomy, reserving the partial gastrectomy for the small percentage of cases in which there was a gastro-duodenal ulceration. As to carcinoma, the number of cases in which he had done a posterior gastro-enterostomy with resection was 1,307, and among these cases twelve—or 0.91 per cent.—developed carcinoma of the stomach. In four of the twelve the carcinoma was present at the first operation; in three the carcinoma was remote from the ulcer; and in five, or 0.37 per cent. of the total, the carcinoma was at the ulcer site. As for the fourth complication—namely, severe anaemia—in his own series after gastro-enterostomy for duodenal or gastric ulcer he had no severe anaemias at all. One such case occurred after gastro-enterostomy and resection for gastric ulcer, and five after partial gastrectomy.

THE SELECTION OF CASES

Dr. EUSTACE CALLENDER said that his own personal experience of gastric surgery had been confined to gastro-enterostomy for the relief or cure of duodenal ulcer. In the cases in which he had ventured to advise operation the procedure had been very generally completely successful, but he gave an account of one case in which there had been complete failure of gastric surgery. His experience led him to believe that the operation was eminently successful in selected cases. There were cases of duodenal ulcer in which, in his opinion, a permanent cure was extremely unlikely without operation; there were others in which the condition could be treated by medicines and diet; and some in which operation should be avoided if possible. A good deal of responsibility rested upon the general practitioner, who knew the patient and his psychology, in selecting the cases that he brought to the surgeon, and also a good deal of responsibility rested upon him in selecting the surgeon.

Sir WILLIAM WILCOX thought that Dr. Ryle's figure of 10 per cent. of anastomotic ulcers was much too high. It occurred in Dr. Ryle's experience because he happened to have selected cases submitted to him. He was inclined to agree with Mr. Walton in his view that posterior gastro-enterostomy was the safest operation for duodenal ulcer, and he also entirely agreed with him in some remarks he had made about the scares concerning carcinoma appearing in an ulcer. Such development was, in his judgement, exceedingly rare, and he thought that, if there was an ulcer, to advance the possibility of carcinoma as an argument for operation was utterly fallacious.

RADIOLOGICAL FINDINGS

Dr. G. VILVANDRE said that the first complication of surgical operation for gastric or duodenal ulcer was to be seen in some cases when the appendix had been removed and, a year or two after operation, the patient still complained of indefinite symptoms of indigestion. In such patients, by taking a careful history, it would be found that at the time of operation for so-called appendicitis he or she was really suffering from symptoms of duodenal ulcer. In his own series of cases such a condition had arisen a good many times—in short, the appendix had been removed on flimsy evidence, while all the time mild symptoms of a duodenal ulcer were

present, but had not been sufficiently investigated to give a definite diagnosis. It followed, therefore, that these patients were submitted in due course to a second operation for duodenal ulcer. In a series of cases which he had examined after gastro-jejunosomy for a duodenal lesion he had on four occasions come across the presence of a well-marked gastric ulcer on the small curvature, some distance above the stoma. It was true that cases of double ulcer—that is, duodenal and gastric—had sometimes been found; and Carman, a famous radiologist in America, had put the number of such cases at 4 per cent. It was difficult to see how a gastric ulcer should follow a gastro-jejunosomy, but whatever the reason the fact remained that such a thing did arise. A more common complication following this operation had been the occurrence of jejunal ulcer.

Mr. DONALD BARLOW thought partial gastrectomy far too radical a measure for ulcer in the stomach. One would have thought that the chief aim would be to rest the stomach, both from physiological movement and from the passage of acid and food. Physiological rest might be obtained by splinting the stomach in some way, possibly by temporary paralysis of the nerve supply by crushing the vagus and allowing regeneration after a certain time, or by strapping the stomach with some sterile preparation. Dr. ERNEST YOUNG pointed out a contraindication to operation in cases common in quite young people with duodenal ulcer, in whom there was rapid emptying of the stomach. These cases almost invariably turned out to be surgical failures.

Mr. W. H. OGILVIE thought it a pity if the meeting terminated in an attitude of too great complacency. The failures were nothing like the simple problem suggested by the majority of the speakers. Few surgeons saw their own failures. In twelve years he had seen only two recurrent ulcers in cases on which he had operated, but in the last five years he had operated for about thirty anastomotic ulcers where the primary operation had been done elsewhere. If the experience of other surgeons was like his own, surgical failure was of no small dimensions. Several surgeons who themselves suffered from the condition were most enthusiastic devotees of medical treatment in their own cases. He attacked that "idol of surgery," posterior gastro-jejunosomy, which in his view did nothing to counteract the cause which brought about the ulceration—in fact, by increasing the rapidity of emptying it made the recurrence of ulcer more probable. The experience of Continental surgeons was that the only method by which acid could be permanently reduced to a level which was really safe was gastrectomy, and this must be radical, at least four-fifths of the stomach being removed. Before such a radical procedure was adopted, of course, medical treatment should be given the fullest trial.

Dr. MAURICE SHAW said that he had seen a relatively large number of failures of gastric surgery, but these did not lead him to underestimate the benefits of operation. Ultimately, success or failure must depend upon the skill with which the cases were selected for treatment, and to a large extent upon collaboration between physician and surgeon. Mr. Walton had not stated whether he removed the appendix as a routine in ulcers, but, whether routine or not, it was a measure which should always be considered. He did not regard the radiological appearances of pyloric obstruction as a certain indication for operation, and he had several times seen cases of apparent pyloric obstruction yield to medical treatment. He had had among his patients a number of doctors who had submitted to operations, with varying results, but he had never heard of a surgeon who had done so—though he was sure there must be such—and he knew of several who had refused.

Dr. J. R. WYLIE presented some statistics from the Miller Hospital relating to 492 operations for gastric lesions, and in a table gave some idea of the frequency of the various post-operative sequelae. In this series there were only two cases of carcinoma in which the surgeon thought the condition had started in an ulcer.

Dr. RYLE, in reply, said that the most frequent and serious of the sequelae was the anastomotic ulcer. In expert hands the figures were low, but it had to be

remembered that gastro-enterostomies were being done all over the country by competent and incompetent alike. It had taken a quarter of a century to realize how serious and frequent were the failures of gastro-enterostomy. Only a few years had passed since partial gastrectomy had become common, and he thought there should be an effort to look ahead and endeavour to estimate how far this experiment—for it was really such—was justified. Great caution should be used in employing partial gastrectomy for small ulcers. Mr. WALTON said that as regards the appendix he did not remove it as a routine; of course, he always examined it, but he did not take it away unless there was definite evidence of disease.

CORRESPONDENCE

The Milk Question

SIR,—In reply to Lord Moynihan's inquiry in your issue of April 21st (p. 727): The evidence on which my statement was based is that in one of our homes, containing about 750 boys, during five years, while they were on a daily pint of raw milk, only one case of non-pulmonary tuberculosis occurred after admission, whereas during the previous five years there were fourteen such cases. These boys must not be taken as being normal for this country, as they consist of what may well be termed a C3 population. They enter these homes for various reasons—poverty, neglect, bad usage, parental alcoholism, etc.—and in quite a number of cases one or both parents have died of pulmonary tuberculosis, so that some might regard them as being a fruitful field for potential tuberculous infection. They are at this particular home because they are, or have been, in need of medical or surgical treatment, and on that account are not fit to be boarded out. We believe that the extra nutrition attained by this means has fundamentally assisted to raise their resistance to tuberculous and other infections. By "tubercle" I mean any lesion which may occur as a consequence of infection with the *Bacillus tuberculosis*.

As the cases recorded were not typed they prove nothing with regard to bovine tubercle, but they do give some indication with regard to tubercle in general; besides, Griffith's and Munro's researches have shown that in the age group (5 to 15 years), as at this home, over 75 per cent. of cases of non-pulmonary tubercle are of human type in those places in the United Kingdom where their work was done.—I am, etc.,

A. H. MACDONALD,
Chief Medical Officer, Dr. Barnardo's
Homes.

Stepney Causeway, E.1,
April 23rd.

The Nutrition Report

SIR,—In your issue of February 24th Dr. Helen M. Jardine comments adversely upon my letter of the week before, but fails to controvert my main contention.

The mere fact that many people suffer from malnutrition and some from subnutrition does not alter the fact that an idle man's nutritional requirements are less than those of the same man engaged in active manual labour, nor the fact that the English as a whole do themselves well. Statistics show that most, except the lowest-paid classes, consume more than their requirements. As regards this question of "malnutrition," most of it is not due to underfeeding, but to a faulty balance in the rations consumed. Besides which the mere fact that a person fails to reach an A1 standard in general condition does not necessarily mean the want of a correct diet, but may be due to ill-health, heredity, congenital defect, or to physiological or psychological reactions to environment other than food.

Dr. Jardine is mistaken when she asserts that I criticized the minimum diets recommended in the B.M.A. Committee's Report. I merely commented on the excellent diet (No. 2) which the committee found in use in well-to-do working-class families in England. And nowhere does the report give "minimum" diets. It gives diets for an average man (with percentages for women and children) doing a moderate day's manual work. This postulates that there are healthy people below and above that average as regards both physique and labour conditions. Therefore some people require less than the 3,000 + 400 calories and others require more. The diets given are not minimum, but average. I presume the committee, when deciding the nutritional requirements of the average man, envisaged him as living in a temperate zone, otherwise its recommendations are very divergent from dietary habits in climatic extremes. The nutritive constituents of the 3,000 calories show the following percentages: 14 protein, 31 fat, 55 carbohydrates (approximately), whereas in Greenland it is 44, 48, 8, and in Java 9, 8, 83, so the inhabitants of these two countries suffer more heavily than the English from malnutrition due to imbalance. To show what man (in a temperate clime) can flourish on, Hindehede put subjects on as low as 1½ oz. (as against 3½ oz.) of protein per day over a prolonged period, and found that they maintained good health and activity (vide Hutchison and Mottram). All of which indicates the possibility of a healthy and active existence on widely divergent proportions of nutritive constituents, under both different and similar conditions, the impossibility of laying down a rigid diet for everyone even in the same environment, and the unwisdom of assuming that all those below standard in physique or general condition are suffering from errors of diet in quantity or balance.

We all agree that the Government should do its part in fostering the well-being of the people, but false deductions and misrepresentations are to be deprecated.—I am, etc.,

Southern Rhodesia, March 25th. D. CAMPBELL WATT, M.D.

Leucocyte Counts

SIR,—Variability in the blood in response to change of environment or of food is essential to constancy of function for any animal that is to survive. The leucocyte count must vary accordingly, yet the count, like the pH, has, on the average, amazing constancy. For both reasons the count is valuable, as is shown by the following case, in which counts were taken for nearly three years. (It is with the differential counts, particularly with the eosinophils, that I have been mainly concerned.)

The case is that of a man with long-standing asthma. In asthma the percentage of eosinophils is usually raised above the normal 3 or 4, with corresponding reduction of the polymorphonuclears. In this patient they reached 70 per cent., the highest I have ever met. As detoxication proceeded and he improved they fell more or less steadily; he has had no asthma for two years. The counts (expressed in percentages) were taken on certain days in the months indicated.

	1931	1932			1933				1934
	Nov.	May	Aug.	Nov.	Mar.	June	Aug.	Nov.	Jan. Mar.
Eosinophils ...	68	70	59	40	54	23	12	7	7 6
Polymorphs....	7	13	18	23	30	38	58	36	69 72
Small lymphs.	23	12	17	20	11	33	20	40	15 15
Large lymphs.	2	5	6	7	5	6	10	17	9 7

In contrast with this steady fall over these years is the rapid variation produced in less than one hour in the same patient by a cold douche following a warm bath.

	Eosinophils	Basophils
Before hot bath ...	63	0.8
Immediately after ...	66	0.6
After cold douche ...	49	0.5
One hour later ...	46	1.0

This change was probably due to the stimulation of the sympathetic and so of adrenaline flow, for fifteen minutes after injection of 10 minims of adrenaline in the same patient the eosinophils fell from 56 to 43 per cent. and from 69 to 59 per cent. The greater reduction after the cold douche seems to indicate the more prolonged effect of the douche than of the injection of adrenaline. Pointing in the same direction is the observation that a cold douche tends to draw out the basophils, as mentioned by Dr. J. A. M. Cameron. In another case the figures were:

	Eosinophils	Basophils
Before hot bath ...	4	2
After hot bath ...	8	3
After cold douche ...	10	4
One hour later ...	4	6

On the other hand, where there is a tendency to toxæmia, and so to eosinophilia, the effect of increasing the toxic load by the injection of 15 grams urea is to raise the eosinophil count. This happened in eighteen out of twenty-three cases so treated—increased eosinophils both in percentage and in total number. In three cases the percentage was doubled, and in one of these it rose from 11 to 22, and status asthmaticus followed for forty-eight hours. On the average there was only slight increase in the total white cell count.

Much else could be added. The lesson surely is not that leucocyte counts are clinically worthless, but (1) that they are of great value if only we attend to the factors making for variation; and (2) that variation in the blood picture is essential if the blood is to keep functional constancy.—I am, etc.,

Glasgow, April 21st.

JAMES ADAM.

Raised Intraocular Tension

SIR,—I am grateful for Flight Lieutenant R. L. Raymond's letter in your issue of April 14th (p. 689) in reply to my criticism of his original article on intraocular tension. He now explains that, although he wrote that the tension in each case was "thought to be higher," he and his colleagues actually had no doubt but that the tension was raised. This does not affect the main part of my criticism, which was to point out that the tension had been estimated merely by digital tonometry. Dr. Raymond will agree that the notes of half his cases described the tension as being only "raised" or "slightly raised." It is surely unwise to be dogmatic about a tension which could not be noted as being definitely raised, when it had only been estimated by a method which is acknowledged by all recognized authorities to be inaccurate and unreliable. An ophthalmologist cannot be sure of his fingers when the tension is only moderately raised, and the estimation of tension must remain a matter of doubt to other people, if not to himself, unless confirmation has been obtained by a less inaccurate method of tonometry. It is therefore not possible to share Dr. Raymond's confidence in his findings.

For the sake of argument, however, let it be imagined that the four cases upon which Dr. Raymond based his conclusions actually did have increased intraocular tension. There is, then, no explanation of the author's further

reply that the point of his article was to demonstrate increased tension with no other symptoms of glaucoma. There can be no justification for this statement in the absence of full clinical details. There was, for example, no information given about the fields of vision. In any case, it is surely a commonplace that increased intraocular tension can, and not infrequently does, occur without any other signs or symptoms of glaucoma at the time of examination. Furthermore, as I have previously pointed out, glaucoma may occur in young people and may cause pain which is referred to the frontal region. There is therefore nothing new in the syndrome reported by Dr. Raymond.

It is possible that the difficulty in following Dr. Raymond's description of his syndrome is due to the fact that he appears to have different views on the subject of glaucoma from those held by modern ophthalmologists. For example, he now explains that his cases demonstrate "pathological hypertension which could not reasonably be called glaucoma" in the absence of other symptoms. Now most, if not all, authorities regard the terms "increased intraocular tension" and "glaucoma" as synonymous. In other words, increased pressure is glaucoma, and there is no such condition as increased intraocular pressure which is not glaucomatous. It is therefore not possible to discuss Dr. Raymond's query as to cause except by consideration of the aetiology of glaucoma, a vast and, as yet, unsolved problem. However, it appears necessary to explain that glaucoma is not a disease *per se*, but a symptomatic condition of which tension is the cardinal sign; it is upon the causes and consequences of the increased intraocular pressure that all the other signs and symptoms of glaucoma depend.—I am, etc.,

London, April 20th.

VICTOR PURVIS.

Theoretical Aspects of Collapse Therapy

SIR,—Dr. F. H. Young's excellent article on the theoretical aspects of collapse therapy in pulmonary tuberculosis, in the *Journal* of April 4th (p. 661), prompts me to ask you for space to refer to some of the recent French views on the subject.

Confining myself for the purpose of discussion to artificial pneumothorax and phrenicectomy only, the indications for, and the results obtained after, these two procedures may, from a mechanical point of view, depend on some or all of the following factors.

1. The intrinsic difference in the action of artificial pneumothorax and phrenicectomy.—A pulmonary lesion is subjected to the physiological tension of the expanded lung tissue and the additional tension during inspiration. An artificial pneumothorax causes relaxation of the physiological tension (static relaxation), inspiratory movements generally still going on, even if somewhat diminished. Phrenicectomy, by abolishing the active diaphragmatic movements, produces dynamic relaxation. The volume of the lung is, however, generally also slightly reduced, causing some relaxation in all directions. The latter factor probably accounts for the improvement sometimes caused by phrenicectomy in upper lobe lesions.
2. The situation of the lesion.—An artificial pneumothorax will often produce poor collapse of the base owing to the common presence of basal adhesions. Phrenicectomy, on the other hand, should clearly benefit basal lesions most. A lesion situated in the centre of the lung will be acted on more favourably (owing to the relaxed tension all around it) than one laterally placed or in the apex. As apical lesions are so much commoner than basal ones, however, the total benefit to be derived from phrenicectomy in the former group may equal or exceed that obtained in the latter.
3. The character of the lesion and the state of the tissues surrounding it.—A cavity or caseous area will benefit more by the relaxation of tension when it is completely surrounded by healthy than by fibrotic or atelectatic lung. On the other

hand, considerable improvement may be obtained in an active fibrotic lesion owing to relaxation of the additional tension caused by the fibrosis involving the diaphragm.

4. The results of phrenicectomy will depend on the extent the patient is in the habit of using the diaphragm. Thus one would expect more benefit in narrow-chested than in broad-chested individuals, in men than in women. Hence also the importance of careful screening before deciding on the type of operation.

5. The presence of adhesions will considerably affect the result obtained. As Dr. Young points out, this factor is also of great importance in phrenicectomy, especially as the presence and extent of diaphragmatic adhesions are more difficult to appreciate.

Even if all these factors are considered beforehand, however, artificial pneumothorax and phrenicectomy still sometimes prove a "toss-up," owing to the unexpected results obtained. For example, E. Dumarest and P. Lefèvre (*Presse Méd.*, 1934, xlii, 498) point out that an apical lesion which at first may benefit from a phrenicectomy owing to relaxation of a downward pull may later retrogress as the result of lateral pulls which before were ineffective owing to the stronger vertical force.

In view of the uncertainty as to the results to be obtained by these operations, the new method of radio-kymography now being studied in France seems of considerable importance. A gridiron plate consisting of x-ray-opaque bars is inserted between the film and the patient's chest. An exposure covering about two respirations is given. The film thus obtained shows in each vertical space small peaks representing the inspiratory and expiratory movements of various organs—for example, rib, edge of cavity, lateral part of diaphragm, etc. It is thus possible to compare and have a record of the movements of lesions in relation to the chest wall and the diaphragm of the same and opposite side (for the effect of any method of collapse on the opposite side of the chest should always be considered). The method is still in its infancy, but offers great possibilities (cf. Léon Bernard, Pellissier, and Silbermann, *Presse Méd.*, 1934, xli, 205; and other references given there).

Finally, in view of the new conceptions in regard to collapse therapy, it might be urged that the expression "compression of the lung" is no longer applicable except when dealing with oleothorax or a pleural effusion associated with a pneumothorax.—I am, etc.,

Paris, April 18th.

G. GREGORY KAYNE.

A Reversible Reducing System of the Lens

SIR,—Until now two "reducing systems" have been found in the lens of the eye. These are the SH groups (glutathione and cystein) and vitamin C (ascorbic acid). The latter forms an irreversible reducing system, while the former are found, in a reduced form only, in all the tissues of the body. It appears, however, to be probable that they are also found in the oxidated form in the lens.

On precipitating the proteins of the lens one finds that the sodium nitroprusside reaction acts more intensely after adding M NaCN. NaCN and KCN have the property of reducing the total amount of glutathione or cystin. So it follows that in the lens the SH groups behave like true reversible reducing systems. If one precipitates the proteins of lenses with the aid of 2/3N sulphuric acid and 10 per cent. sodium tungstic acid or 10 per cent. trichloroacetic acid, and one adds to the filtrate a solution of silver lactate as has been described by Folin, one finds not only the glutathione and the vitamin C, but also a yellowish substance. This substance may be dissolved in 0.25 per cent. hydrochloric acid, and shows in light of short wave-length (3,660 A.U.)

a strong fluorescence of yellowish-green colour. This fluorescence is lost after strongly reducing the substance. On making this solution basic and adding acid again to it, it is possible to extract the substance with the aid of chloroform. After evaporating the chloroform extract one may obtain a solution in water.

It is clear, therefore, that this substance shows all the properties which are peculiar to those substances which are isolated from tissues of rats and tumours by Bierich and Rosenbohm. These authors consider the substances to be identical with the yellow oxidation ferment of Warburg and Christian and with vitamin B₂ of Kuhn, Wagner-Jauregg, and György.

A considerable amount of this yellow oxidation ferment may be found in the lens, which is revealed by the fact that a very weak solution—1 in 7,000—still shows the fluorescence. It appears that there is a decrease of it in the lenses of elderly patients. In lenses affected with cataract the amount of vitamin B₂ is diminished or disappears. Bierich and Rosenbohm take it for granted that a very low E_h potential is particular for this yellow oxidation pigment. This E_h potential should be the lowest of all physiological reducing systems hitherto known. It covers the range of potentials measured in mammals by an anaerobic method. It is quite clear that a real reversible system of oxido-reduction is of fundamental importance for the mechanism and continuation of the internal respiration of the lens.—I am, etc.,

Hypochondriasis

SIR,—Touching the vexed question of hypochondriasis which has recently been discussed in the *Journal*, may I submit that clinical classification is the only scientific means of understanding the various morbid conditions of which it is a prominent symptom? It so happens that I have lately been interested in the clinical analysis of the acute and subacute mental crises common in private practice, and consequently can give some figures which will throw light on the subject. I stress the importance of investigating "crises"; so-called "chronic hypochondria" really represents nothing but a bin into which are cast all sorts of unclassified depressive states.

I find that out of one particular series of 514 medico-psychological crises observed by myself 100 exhibited hypochondria as a prominent feature. Of these, sixty-five were undoubtedly manic-depressive in type, the remaining thirty-five being anxiety states. The incidence of hypochondriacal conditions—as occurring in one particular practice at any rate—is shown by reference to the whole series. Tabulated, my analysis gives the following results:

Manic-depressive psychoses	276
Acute anxiety states (psychoneuroses)	110
Schizophrenic-paranoid cases	77
Organic and toxic group	51
Total	514

The 276 manic-depressive psychoses are represented by:

Melancholia (including involuntal types), 178; manic and hypomanic states, 33; hypochondria, 65.

These latter represent mild manic-depressive states in which anxiety associated with health matters was the most prominent symptom. Among the 110 acute anxiety states, all definitely representing psychoneurosis, there were thirty-

APRIL 28, 1934]

CORRESPONDENCE

five in which anxiety was predominantly associated with health.

Clinically, where hypochondriasis is not an anxiety state (psychoneurosis) it represents manic-depressive psychosis. The practical point is that, where it represents an anxiety state, direct psychotherapy of the personal influence and suggestion order will work miracles; but where it is of the manic-depressive type we find ourselves up against a self-limited disease not very amenable to treatment of any kind. Nevertheless, even here encouragement and personal support will do much to better the patient's lot.—I am, etc.,

EDWIN HOPEWELL-ASH.

London, W., April 16th.

Monilia in the Sputum

SIR,—With reference to Dr. Bertram Jones's paper—"The Significance of Monilia in the Sputum"—in the *Journal* of March 3rd (p. 368), the work was, as stated, undertaken after I had consulted with Dr. S. Roodhouse Gloyne, and the original suggestion agreed to was the cultural examination of saline washings obtained through the bronchoscope from the affected alveoli and bronchi.

I do not think that one is splitting hairs in pointing out that "monilia in the sputum" differs from bronchomycosis, as "pneumococci in the sputum" differs from pneumonia. We have to remember that monilia can be grown from tea and from tobacco-dust—these are tropical monilias; unfortunately, we are unable to differentiate these monilias from those which are derived from cow's milk.

With reference to Dr. Lawrence P. Garrod's letter (*Journal*, March 17th, p. 504), and the presence of monilia in pulmonary tuberculosis, this brings forward the factor of pyogenic organisms. Monilia are pyogenic, and the difference in outlook between surgical and medical tuberculosis lies in the fact that the patient suffering from tuberculosis of the lung usually presents himself when suppuration has become only too evident.

To stress the action of monilia I should like to quote Sampson, who states that "the lungs of tuberculous cattle often contain blastomycetes and other fungi, and that the blastomycetes are indistinguishable from those isolated from human tumours. They seem to render the tuberculous infection more virulent."

We in Jersey, dealing with tuberculous lungs, have dealt with the monilia present; coincident with this, the deaths from tuberculosis of lungs have fallen gradually from 69 in 1922 to 34 in 1932.—I am, etc.,

P. JANVRIN MARETT,
Lieutenant-Colonel R.A.M.C. (ret.).

Jersey, April 12th.

Pathogenesis of Cancer

SIR,—I think Dr. Cronin Lowe (April 14th, p. 687), in saying that the observations and findings of Dr. Shaw-Mackenzie and other investigators "seem to be strangely forgotten," has missed the point. These findings are most valuable as showing the workings of the cancer cells, and especially as aids in the diagnosis of cancer. But surely the deficiency in the lipolytic enzyme in the blood is the effect, not the cause, of the cancer, since the enzyme reappears after removal of the cancer.

As Dr. Lowe says, not everyone who is exposed to cancerous agencies falls a victim. All the workers exposed to industrial cancer-irritants (soot, tar, paraffin, x rays, amine, etc.) do not succumb; so there must be some "soils" which are immune, but, as yet, the immune factor has not been discovered. One "soil" has had the

reputation, in my experience justly, of being comparatively immune—that is, the "soil" which predisposes to, or harbours, tuberculosis. I wonder if blood or serum from a robust person of tuberculous stock would retard the growth of an inoperable cancer; or, if the comparative immunity is due to the tubercle bacillus, and not innate, whether a toxin-antitoxin form of tuberculin might do so—much as malaria improves general paralysis, and Coley's erysipelas sarcoma. But blood or serum from cases of "spontaneous cures"—if there are such cases—would, of course, be preferable.—I am, etc.,

M.D.

South Wales, April 16th.

Heredity and Scoliosis

SIR,—I do not wish for one moment to detract from the illuminating article by Dr. Gadland upon heredity and scoliosis (*February* 24th, p. 328), and I do want to compliment him upon the work he has done in this respect, but I must emphasize the fact that such cases must be rare in comparison with the numerous other conditions that produce scoliosis. Heredity as being aetiologically concerned in scoliosis is not mentioned at all in the textbooks, and this rarity is confirmed in the out-patient departments of hospitals and in private practice. Lamarck, a century ago, enunciated the theory that acquired modifications are being continually produced and perfected by any organism during life, and so that each generation will be rather better adapted to its surroundings ("and purposes in life") than its predecessor—for example, the great length of the neck of the giraffe can be explained in this way by the continued striving through many generations to reach the higher leaves on the trees. Yet it has to be proved that a degenerative condition as scoliosis could be designated as an acquired condition. To my mind the inherited condition of scoliosis arises from the cumulative effect through generations of bad hygienic conditions. This again is confirmed in actual practice, as the patients suffering from this deformity in the great majority of cases come from our slum population.—I am, etc.,

CLEMENT BELCHER, M.B.
B Ch., D.P.H.

Birmingham, April 1st.

Conjugal Pulmonary Tuberculosis

SIR,—The statement that pulmonary tuberculosis is not communicable from adult to adult, from husband to wife, and vice versa, has so often been made—more especially by Harley Street, and also occasionally by those who should know better, such as tuberculosis officers, who come into constant contact through many years with entire family histories—and my impression has been so very different, that I decided to spend spare moments in dipping into dispensary records in order to ascertain whether I could substantiate my impressions.

I have not made a survey of all cases coming to the dispensary, but have noted down those cases coming to the minds of myself and of the dispensary staff, and can by these means alone account for forty instances in which there seems definite reason to believe that pulmonary tuberculosis passed from one to another of a married couple. The reason why this fact sometimes escapes recognition by the physician is, perhaps, the length of time which elapses before the infection is brought to light, and that the two victims are not seen at hospitals or in consulting rooms as they are at dispensaries, where the tuberculosis officer is personally acquainted with

all the sufferers from the disease for many years in succession.

The details of the forty cases are as follows. No cases have been included in which the sputum was not positive for tubercle bacilli (except where the patient died many years ago and the fact is not available). In twenty-one cases the husband was first notified, and in nineteen cases the wife. In twenty-five cases both husband and wife are dead, in three cases both are alive, in six the husband only is dead, and in six the wife only is dead. The period which elapsed between the notifications is, as accurately as can be ascertained, shown in the following table.

Period Elapsing between Notification of Husband and Wife

Period in years ...	1 year and under	2	3	4	5	6	7	8	10	14	16	29
Number of cases ...	6	4	4	6	3	3	4	4	1	3	1	1

Thus only 15 per cent. came to the knowledge of the physician during the first year after the notification of the first partner, and all these couples are dead, the infection having been acute. The shortest period between the notifications was eight days. It will be observed that in 70 per cent. of the cases a period of two to eight years elapsed between the notifications. In the remaining 15 per cent. the period between the notifications amounted to from ten to twenty-nine years. It may be contended that in twenty-nine years the infection may well have been contracted from another source; in this instance the man is alive, aged 59, suffering from chronic pulmonary tuberculosis (T.B.+), and was notified on September 5th, 1931, having lost his first wife from pulmonary tuberculosis in 1902.

It would aid the efforts of the dispensary staff if patients were not assured at hospitals that there is no danger of infection between married couples. They might then be more willing to take necessary precautions at home.—I am, etc.,

ROSE JORDAN, M.D., D.P.H.

Blackheath, S.E., April 6th.

Wanted: Bee Venom for Rheumatism

SIR.—Can any member of the B.M.A. assist the Devonshire Royal Hospital, Buxton, to obtain standardized bee sting for the treatment of arthritis, fibrositis, and neuritis? From January, 1932, to August, 1933, we have used bee sting at the Devonshire Royal Hospital, made by Wolff, under the name of apicosan, and have obtained excellent results; but in August, 1933, the Customs notified the hospital that an import licence was required, and the Ministry of Health wrote stating the necessity for a licence. On December 9th, 1933, we wrote a joint letter to the Ministry of Health, stating that we had found apicosan of definite value in the treatment of certain rheumatic conditions, and that we wished to continue our investigations. We offered to allow them to investigate our cases. There was no reply to this letter. After waiting three weeks a letter was sent asking for a reply. The Ministry replied to the last letter by asking for particulars of manufacture, and all the available information was forwarded to the Ministry; but we are still not allowed to obtain supplies. It is interesting to note how the Ministry of Health obstructs a genuine attempt at research into the treatment of rheumatism and allied diseases, and prevents the use of well-recognized remedies for English hospital patients suffering from the above diseases.—We are, etc.,

Medico-Legal

THE DUTIES OF THE MEDICAL WITNESS.—V

PROFESSIONAL SECRECY*

Medical men are often asked in cross-examination questions which they cannot answer without divulging information they have learnt in the course of their professional relationship with a patient. The medical man recognizes a moral and ethical duty to his patient to maintain strict secrecy concerning anything which he learns through his position as medical adviser. That duty is not recognized by the law of this country. Consequently, when a medical man is giving evidence, and is asked a question which he cannot answer without revealing a professional secret, the law is that he must answer the question if ordered to do so by the judge. Medical men have long protested against this rule, especially as they see that it does not seem to apply to legal advisers. Their discontent has aroused sympathy in eminent lawyers. For instance, the learned editor of *Taylor on Evidence* says:

"The rule has been confined, with perhaps understandable strictness, to communications which pass between a client and his legal adviser, and the protection has not been permitted to extend to any matters communicated to other persons, though such communications were made under terms of the greatest secrecy."

He instances clergymen and medical men. In *Greenough v. Gaskell* (1833) Lord Brougham said: "It might not be very easy to discover why a like privilege has been refused to others [than lawyers], especially to medical advisers." This, moreover, was a hundred years ago, when medical men were not trusted nearly as fully as they are to-day.

One of the most lamentable results of this rule is that it goes far to counteract the confidence which has been so carefully built up by the Government among an especially timid class of the community—patients with venereal disease. Under the statutory regulations governing the treatment of venereal disease in the clinics of local authorities, the strictest secrecy is maintained concerning the patients who attend. Only if this secrecy is guaranteed under statute can the State hope to render its scheme of treatment effective. Nevertheless, the pledge of secrecy cannot be put against the requirements of justice as interpreted by the courts.

In *Garner v. Garner* (1920) a lady petitioned for the dissolution of her marriage. Adultery by the husband was proved, and the cruelty which she alleged was that he had infected her with syphilis. One of the medical officers of the Western Hospital was called to give evidence of her disease. He handed to the judge trying the case (Mr. Justice McCardie) a letter from the chairman of the House Committee, stating that the hospital had adopted the national scheme for dealing with venereal disease, and enclosing a copy of the statutory regulations. The judge read these communications aloud, but added that they could not override the obligation of a medical witness to give evidence. He said that the witness was desirous of assisting the scheme in every way, and wished loyally to maintain the secrecy which rightly rested upon him; he would, however, appreciate that in a court of justice there were even higher considerations than those which applied with regard to the position of medical men. Apart from the obligations which might be imposed on medical men by the order of His Majesty's judges, it was desirable that there should be the most loyal observance of the confidence which was reposed in them by patients. He was glad to say that the history of the medical profession was most honourable, and it was to be hoped that its members would always retain the confidence reposed in them.

While the witness and medical men in general were probably grateful for Sir Henry McCardie's remarks, these could not have done much to sweeten the pill which

* The first of this series of five articles by a legal correspondent appeared on March 3rd (p. 407), the second on March 17th (p. 588), the third on March 31st (p. 600), and the fourth on April 14th (p. 692).

APRIL 28, 1934]

DUTIES OF THE MEDICAL WITNESS

he administered. This case is typical of many in which the doctor finds his duty to his patient conflict with his duty to justice.

Another common position is that of the general practitioner who is consulted by a woman suffering from the effects of an unsuccessful attempt at abortion. If he is afterwards called as a witness for the Crown against her, he will be compelled to state what he knows on pain of being committed to prison. I know of no case in which a medical man has accepted the penalty rather than disclose confidence. The choice is one for the individual, but few fair-minded persons could be found to condemn a doctor who obeyed the order of a judge to abandon the claims of professional ethics in favour of the claims of justice. It is not fair that a medical man should be placed in this position, but there seems no prospect that the dilemma will be removed in the near future. The witness should always make a strong protest; if the judge is not a very relevant one the judge may suggest to counsel that he should waive his right to ask it. After the witness has been cross-examined counsel for his side may "re-examine" him—that is, ask questions on points raised in cross-examination—in order to suggest a construction favourable to his own case. The judge may then put questions, but if he does not the witness is free. This is the moment when he or his counsel should ask for him to be released, unless he wishes to hear the rest of the case.

CONSULTATION BETWEEN MEDICAL WITNESSES

A practice which would go a long way towards reducing conflict in medical evidence, and, what is more, to discouraging partiality in medical witnesses, is that of conference between the medical witnesses to be called by the two sides. The effect of such a conference would be, not that any of the witnesses would alter his evidence, but that doubtful points might be cleared up and in agreement attained, so that the witnesses would be in a position to put before the court the considered medical opinion on the case from a particular aspect. If this result could be achieved it would undoubtedly be a great help to the judge and counsel. Sir William Willox has expressed himself strongly in favour of this procedure.

A letter in the *British Medical Journal* (1930, ii, 667) gave a good illustration of the possible value of consultations between medical witnesses.

A workman fell at work, and broke both bones of the leg just above the ankle. About nine months later, after he had been examined jointly by the employers and his own doctors, the employers stopped paying compensation, and the workman started arbitration proceedings in the county court. He pleaded that, although his fracture had healed perfectly, he was suffering from flat-foot due to the fall. He had not been suffering from flat-foot before the accident, and more than a year after the accident. His panel doctor, giving evidence, said that he had noticed the flat-foot at the joint examination, but had not called the attention of the employers' doctor to it. When the judge asked him why, he answered, "The man's foot was there, and I did not think it necessary to point it out." The judge decided against the workman's claim at the end of the case strongly warning to doctors that workmen in compensation cases are to a large extent in their hands, and they are responsible for seeing that sound and adequate advice is given.

As the writer of the letter points out, those familiar with the medical procedure in workmen's compensation cases will easily understand how such a regrettable position is reached. The two doctors meet, not as scientifically minded persons concerned only to arrive at the real facts and their causes and results, but as hostile witnesses, each one placing the success of his own side first. Hence, instead of full discussion of all the points and their possible issues, each may be trying to give as little information as possible about his own views while endeavouring to detect the weak points in the presentation of the case by the other side. The writer adds that the policy of the British Medical Association has

always been to encourage a frank and complete interchange of views between medical witnesses. This was a case of comparatively minor importance, but the principle is the same in a case where thousands of pounds are claimed for personal injury, or even when a man is being tried for his life.

THE NEW PROCEDURE RULES

An important step towards making general the practice by which medical witnesses for both sides meet and discuss the evidence has been taken by the High Court in framing the rules which are commonly called the "New Procedure." These rules were introduced in the summer of 1932 in order to quicken up litigation. They are mainly directed towards claims for damages for personal injury—which is more or less synonymous in these days with motor-car accident cases. A judge trying a New Procedure case may refer to an expert referee matters concerning the extent and permanence of any injury caused or alleged to have been caused by the negligence of a party. The special referee will presumably be a doctor, and may find it advisable to examine the injured person in the presence of the doctors of both sides. This provision should often enable the medical witnesses to agree, and avoid the necessity for any of them being called. The referee furnishes a report to the court, and both parties are allowed to see it, though they need not accept it, and it is at the disposal of the judge for his assistance in trying the case. Under another rule the judge can limit the number of expert witnesses called by each side. When the judge hears the summons for directions—the preliminary hearing at which he determines the general lines on which the case shall be conducted—and fixes the date for the trial, he often asks the parties whether they have agreed their medical evidence, and, if not, whether they cannot do so. If they cannot, they ask him for leave to call experts, and he decides how many are necessary. He may at his discretion decline to allow the cost of more than those whom he considers necessary, and the result is an effective check upon the tendency to multiply the medical evidence in the hope of making the other side pay for it.

Counsel, when deciding on the witnesses he considers ought to be called in a case, is often apt to forget that the judge is a person of exceptional intelligence and experience. The other day the New Procedure judge was hearing a summons for directions in a claim made by a boy for peculiarly bad injuries to the face caused by a collision with a motor lorry. The injuries had healed, but there was considerable disfigurement. Counsel for the boy desired to call a plastic surgeon to testify to the extent of the disfigurement. "Won't it do if I look at it," asked the judge plaintively, "or do you want to call an R.A.?" This was an instance in which the judge could quite well decide the extent of the disfigurement, but a plastic surgeon could speak about the possibilities of improving matters. The judge willingly agreed that this was outside his scope, and allowed the costs of the witness.

(Concluded)

The Lord Mayor of London (Sir Charles Collett), in presiding at the ninety-eighth annual meeting of the governors of St. Mark's Hospital, said that the last year was one of great activity and increasing work in all departments of the hospital; nearly 1,000 patients had been admitted to the wards and over 1,200 operations performed. He referred to the reconstruction and extension scheme, whereby it was proposed, in order to celebrate the centenary of the hospital's foundation, to brate the number of public beds, to build a nurses' home, to provide a self-contained paying patients' block, to install a second operating theatre, and to improve the cancer research, x-ray, and out-patients' departments. The cost of these extensions would be £60,000. The appeal was launched in January, and £2,300 had already been received.

Obituary

LADY BERRY, M.D.

Frances May Dickinson Berry, whose death occurred on April 15th, was the daughter of Sebastian Stewart Dickinson, a barrister, who after practising with great success in India returned to England and settled down in the village of Painswick, at the head of a beautiful valley in the Cotswold Hills, where he married the Squire's daughter. According to the custom of those days, Miss Dickinson was educated at home until the age of 16, when she was sent to the Continent; she spent two years in a school in Orleans, a year at Dresden, and several months in Spain, and acquired an excellent knowledge of languages, which was later to be turned to such good account. For the next three or four years she and her sister studied art, and her accomplishments in this direction were not inconsiderable. The artist, however,

soon felt the need for more serious work, and she began to study medicine at the Royal Free Hospital. At that time women medical students had to meet much popular prejudice as to what was a proper occupation for a "lady," and in many cases academic distinctions were gained only at the cost of some sacrifice of feminine grace in the course of the struggle, the crusade for freedom sometimes finding expression in the wearing of odd clothing of a pseudo-masculine character and the

cultivation of an aggressive manner which often gave offence. It is therefore gratifying to find that, according to contemporary records from the hospital, Miss Dickinson was distinguished among her fellow-students for her personal charm and her good taste in dress. It was not long before these qualities caught the discerning eye of a young demonstrator of anatomy, James Berry, who not only succeeded in giving her a sound knowledge of his subject, but was fortunate enough to win her heart.

After qualification she held resident appointments at the Belgrave Hospital and at the New Hospital (later renamed in memory of Elizabeth Garrett Anderson), and the experience so gained enabled her to pass with honours the degree of Bachelor of Surgery shortly after taking the M.D. Lond. At the Belgrave Hospital she made the acquaintance of Mr. Clinton Dent, who aroused her interest in mountaineering, and she was the first woman to reach the summit of a particularly difficult peak in Norway. For many years after this she and her husband visited the mountains and together climbed many ranges in the Austrian Alps, Pyrenees, and Carpathians; they made their arduous way with rope and alpenstock to the top of the Gross Glockner and explored the glaciers around Saas Fee. Outdoor exercise had been a tradition at Painswick, and the strain of work in London was relieved by horse-riding in Hyde Park—a form of recreation which she persuaded her husband to take up, so that early in the 'nineties the pair might often have been seen cantering down Rotten Row in the morning. She also taught him to ride a bicycle, and this led to many cycling holidays abroad, when they explored the greater part of Europe and crossed many formidable mountain passes. Not long after the assassination of King Alexander of Serbia, in 1904, they visited that country, to which they returned soon after the beginning of the Great War, when typhus broke

out in the valley of the Morava River. The present writer had the privilege of serving in the Berry Unit at Vrnjatschka-Banja, and can bear personal testimony to the success with which Lady Berry adapted herself to the strenuous conditions of life on active service, and the value of the work which she accomplished there. Her sympathetic understanding of the political entanglements in the Balkans led her to publish a book on the Slav subjects in the Austrian Empire, and she collaborated with her husband and other members of the unit in writing the story of their work in Serbia. Her interest in the country continued unabated after the war, when she and her husband founded a scholarship to enable women students from Yugoslavia to study medicine in London. It may be mentioned in passing that Lady Berry's sister, who is an accomplished artist, shared this interest in the Balkan peoples, and founded in Travnik a most successful technical school, lately moved to Belgrade, where the natural talent of the Slav in making beautiful embroidery, furniture, and decorative work is trained and organized, and a market found for the articles so produced. For many years Sir James and Lady Berry spent their holidays in exploring odd corners of Europe and in taking photographs, many of which were made into lantern slides and used to illustrate the "travel talks" which were delivered to parties of friends in Wimpole Street: one of these pictures would usually be selected for reproduction in the next annual Christmas card, which was further embellished by a few witty verses over the signature, "F. M. D. B." A collection of these cards was printed and circulated in the form of a small book among friends of the family a few years ago, and forms a most interesting souvenir of some thirty years of travel and adventure.

Lady Berry was an excellent hostess, and was an active member of the Lyceum Club, where she often took the chair at dinners and receptions: her wit and vivacity were greatly appreciated on these occasions, and she acquired a good command of the art of after-dinner oratory. Her interest in foreign affairs led naturally to her early and sustained support of the League of Nations and of other organizations for the promotion of international co-operation. Since her retirement from practice a few years ago she lived in the village of Dunsmore in Buckinghamshire, where she became a well-known figure, going for long walks in the district of Wendover, usually accompanied by her two black poodle dogs. She was fond of the woods and of wild flowers, and was always a welcome visitor in the homes of the country people, whose interests she made her own. She enjoyed the best of health up till the last few weeks, and used to say that she had never had so much as a headache in her life: only two days before her death she walked for nearly a mile through the woods.

The funeral service was of a very simple character; it was conducted in the village church of Little Hampden, and was attended by a few members of the family and personal friends and by many of her neighbours in the country. Among the floral tributes to her memory was a wreath from the President, Council, and Fellows of the Hunterian Society, of which she was the first woman Fellow. The churchyard in which she was laid to rest is close to the historic Little Hampden Common, and overlooks the fields and woods which she loved so well.

[The photograph reproduced is by Lafayette Ltd] D. C. N.

The following well-known foreign medical men have recently died: DR. ANGEL BRIOSO VASCONCELOS, professor of dermatology and hygiene at the medical faculty of Mexico, and DR. ARTHUR LAMBERT CHUTE, associate professor of urology at Tufts College Medical School, Boston, and president of the American Association of Genito-urinary Surgeons.

APRIL 28, 1934]

THE LATE DR. JAMES ANDERSON

Dr. W. F. J. WHITLEY, county medical officer for Northumberland, writes:

By the death of Dr. James Anderson of Seaton Delaval, of whom an obituary notice appeared last week, the profession has lost a very fine and representative type of general practitioner. Dr. Anderson took a very great interest in everything appertaining to the work of the St. John Ambulance Association. He was an enthusiastic lecturer on the subject, and devoted much time to training students, examining candidates for certificates, and adjudicating at competitions, at which he was a very popular judge. It was a great pleasure to watch him at these contests, especially in the colliery districts of Northumberland and Durham, in some of which he had adjudicated annually for the past thirty years. It speaks volumes for the confidence reposed in his judgement that his decisions were accepted year after year by local aspirants for cup honours without demur or question, and was for some years assistant county commissioner, and it gave great satisfaction to his many Ambulance friends when he was appointed a Commander of the Order of St. John of Jerusalem. It is asserted that he was the first medical man to go down a pit for the purpose of rendering surgical assistance to injured miners, and he introduced into this district the Low Moor jacket, which is a convenient form of vertical stretcher. At the outbreak of war Dr. Anderson was actually in camp as medical officer to the Northern Cyclists' Battalion, and very soon proceeded over-seas, where he remained until demobilization at the conclusion of hostilities. He was acting major and adjutant of his unit, retiring with the rank of captain. He was a prominent member of the British Legion, and took a great interest in its work. As a raconteur he was particularly successful. His wide and cultured reading gave him a very catholic view of life. He was possessed of a very fine library, and one seldom applied to him in vain for literary assistance; if he was not himself able to supply the information he knew where it could be found. An old member of the British Medical Association, he always endeavoured, if possible, to attend the Annual Representative Meeting, making it part of his holiday.

CHARLES PORTER, M.D. R.U.I.

Late M.O.H. for Johannesburg
On March 14th, a few weeks before his seventieth birthday, Dr. Charles Porter, late medical officer of health for Johannesburg, died of heart failure following coronary thrombosis at Muizenberg, Capetown, South Africa. Charles Porter was born in Cork in 1864, was educated there, and subsequently in Dublin and at University College, London. Intending to enter the Army or the Indian Medical Service, he graduated M.D., B.Ch., B.A.O. in 1889 (with honours and an exhibition). His sight proving insufficiently good for the strict tests of the home and Indian military medical services, he took a certificate in mental diseases and the diploma in public health at Cambridge. In 1890 he was appointed assistant medical officer of health for East Kent, and in 1893 became medical officer of health for Stockport, a post which he held for five years. It was there that he showed his thorough grasp of public health matters, and under his stimulus Stockport became one of the first corporations to deal effectively with the question of maternal education. A health visitor was appointed to pay occasional visits to each school in order to supplement by demonstration the instruction given by the regular teachers. This work, initiated by Dr. Porter, was carried on by his successor. In 1898 Dr. Porter was called to the Bar, and in 1901, whilst vice president of the Society of Medical Officers of Health, he was invited by the Chief Medical Officers of the Local Government Board and of the London County Council to apply—as he did successfully—for the post of medical officer of health for Johannesburg.

Under the administration of Johannesburg by the first municipal council, nominated by Lord Milner, were laid the foundations of a public health service second to none in Africa. Dr. Porter's organization has stood the test of time, and has achieved results that are both encouraging and noteworthy. During his tenure of office the European death rate of Johannesburg decreased by 31 per cent., the incidence of enteric fever by 87 per cent., and the mortality from pneumonia by nearly 50 per cent. The immense improvement made in the mining capital during the last twenty years is often attributed to the pioneer efforts of Dr. Porter, who changed what was practically a slummy barrack town into a clean and sanitary city. Its progress offered a striking proof of his close touch with modern methods and scientific thought, while his service on various commissions was valuable in introducing highly necessary legislation, both provincial and Union. Besides organizing an efficient public health department, he put through schemes for purification of the city's water supplies, child welfare, disease prevention, control of milk supply, and disposal of refuse and sewage. In addition, he acted as consulting adviser to the Rand Water Board, member of the Public Health Council of the Union, specialist adviser in military hygiene to the Union Defence Force, and member of numerous Government commissions relating to education, hospitals, mining regulations, housing, and prisons. Dr. Porter was a man of broad, generous sympathy, plain-spoken, sincere of purpose, honest, and unselfish. His character and the influence he always exerted on behalf of progress and improvement won him the respect of all who worked with or under him.

Dr. WILLIAM SANDERSON, who died on April 15th at his residence in Croxeth Grove, Liverpool, was born in 1882, and received his medical education at Edinburgh, where he graduated M.B., Ch.B. in 1903, and won the Sheen medal for surgery. After holding house appointments at the Stanley Hospital, Liverpool, and the Southport Infirmary, he began general practice in Southport in 1907, specializing in diseases of the ear, nose, and throat. During the war he continued his specialty in the Myrtle V.A.D. Auxiliary Hospital, Liverpool, and for two and a half years was similarly occupied in the R.A.M.C. He was appointed honorary laryngologist and aurist to the Royal Southern Hospital, Liverpool, and the Southport Infirmary. Among his appointments were those of surgeon to the Liverpool Ear, Nose, and Throat Clinic, senior honorary aurist to the Ear and Eye Infirmary, Liverpool, and laryngologist and aurist to the National Union of Teachers and the National Association of Local Government Officers. He was a Fellow of the Royal Society of Medicine. He joined the British Medical Association in 1908, and contributed articles to the *British Medical Journal* and elsewhere on throat and nose work. He was a swift and skilful operator, and won high appreciation for his diagnostic ability and resourcefulness.

The Services

DEATHS IN THE SERVICES

Colonel William Henry Wilson, D.S.O., Bengal Medical Service (ret.), died at Terquay on March 18th, aged 69. He was born on October 7th, 1864, at Rugby, in the Central Provinces of India, and took the D.P.H. in the Central Provinces of India in 1886, also subsequently graduated M.B. Lond. in 1895, and took the D.P.H. in the London Colleges in 1911. He entered the Indian surgical service on March 31st, 1887, taking the Montrose surgical prize in the Army Medical School at Netley, and became lieutenant-colonel after twenty years' service, and retired on November 15th, 1908. When the war of 1914-18 began he rejoined for service, and held the post of registrar of the Pavilion military hospital for Indian troops at Brighton till

the hospital was closed in 1916, and afterwards in various other parts, and for his services was promoted to honorary colonel on January 1st, 1919. From October 15th, 1919, to April 15th, 1922, he served as a temporary lieutenant-colonel in the R.A.M.C. His whole service in India was passed in military employment: from 1903 to 1907 he was Secretary to the P.M.O. of His Majesty's Forces in India. He served on the North-West Frontier of India in the Hazara campaign of 1888 (medal with clasp), the Miranzai expedition of 1891, and the Tochi campaign of 1897-8 (medal with clasp). When the South African War began he was sent in charge of an Indian field hospital to Natal, and served in the operations in Natal, including the action at Lombard's Kop and the defence of Ladysmith, and in operations in the Transvaal; was mentioned in dispatches in the *London Gazette* of February 8th and September 10th, 1901, and received the Queen's medal with three clasps, and on June 26th, 1901, the D.S.O.

Lieut.-Colonel George Holden Sylvester, R.A.M.C. (ret.), died at Bonnemouth on March 23rd, aged 77. One of the seven sons of the late Samuel Augustus Sylvester of Tonbridge, he was born at South Petherton, Somerset, on October 25th, 1856, was educated at Bart's, and took the M.R.C.S. and L.R.C.P. Lond. in 1878; also, subsequently, the F.R.C.S. in 1886, and the D.P.H. of the London Colleges in 1889. Entering the Army as surgeon on July 31st, 1880, he became lieutenant-colonel after twenty years' service, and retired on October 19th, 1907. He served throughout the South African War of 1899-1902, first as staff officer to the P.M.O. at Army Headquarters, and afterwards, from February 12th, 1901, as P.M.O. of a general hospital; and took part in operations in the Transvaal and Orange Free State, was present at the actions of Paardeberg, Poplar's Grove, Driefontein, Pretoria, and Johannesburg, and received the Queen's medal with four clasps and the King's medal with two clasps. He was re-employed in the war of 1914-18, from February 1st, 1915. Colonel Sylvester had been a member of the British Medical Association for forty-six years. His younger brother, Dr. H. M. Sylvester, who practised at Leiston in Suffolk, died in 1927.

Surgeon Lieutenant Commander Annesley George Lennon Brown, D.Sc., R.N., died suddenly at Blackheath on April 8th. He was educated at Westminster Hospital, and took the L.M.S.S.A. in 1922. Entering the Navy as surgeon lieutenant on October 25th, 1922, he was promoted to surgeon lieutenant commander on October 25th, 1928.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week passed new clauses and schedules of the Unemployment Bill. The Budget Resolutions were down for discussion on report.

The Marriage (Extensions of Hours) Bill was read a third time in the House of Lords on April 18th, and a proviso added that the Bill should not apply to Scotland or Northern Ireland except in so far as it amends the Foreign Marriage Act, 1892. The Bill extends the legal hours for solemnizing marriages to 6 p.m. The Marriage Act (1886) and Foreign Marriage Act (1892) Amendment Bill has also passed the Lords.

The House of Commons on April 20th gave third readings to the Registration of Births, Deaths, and Marriages (Scotland) Amendment Bill, the Workmen's Compensation Act (1925) Amendment Bill, the Supply of Water in Bulk (No. 2) Bill, and the Arbitration Bill. The last two had already passed through the House of Lords.

On April 20th the Protection of Animals Bill passed through committee of the House of Commons, was reported, and read a third time. During the committee stage the Bill was amended to make it apply to untrained horses and bulls, these names having the same application as in previous Protection of Animals Acts.

The Birmingham United Hospitals Bill was read a second time by the House of Commons on April 23rd without discussion and sent to a select committee.

The Water Supplies (Exceptional Shortage) Bill and the Licensing (Standardization of Hours) Bill both passed through committees of the House of Commons on April 24th.

Mental Deficiency in Prisoners

The report of the Commissioners of Prisons and the Directors of Convict Prisons for 1932 was issued to members of Parliament on April 24th. The Medical Commissioner, Dr. W. Norwood East, deals in his report with the diseases of prisoners. In a section on mentally affected prisoners he remarks:

"It is suggested that whenever justices are in doubt in regard to the mental condition of an offender the fact should be determined before sentence, and that the contrary practice is undesirable and may be inequitable. The request by the justices for a report at the expiration of the sentence is usually unaccompanied by any information, and the prison medical officer is left entirely ignorant on the matter."

The Medical Commissioner announces that action is about to begin on the lines of the recommendation, by the Persistent Offenders Committee, that a medical psychologist should be attached to one or more penal establishments to carry out psychological treatment in selected cases.

Suicides from Gas Poisoning

On April 24th Mr. LECKIE asked the President of the Board of Trade whether, in view of the increasing number of suicides in gas stoves, he would make inquiries as to the practicability of introducing into coal gas at the place of manufacture some pungent or disagreeable chemical agent, which would render it more difficult for anyone attempting to commit suicide in this way to do so. Mr. RUXEMAN replied that the practicability of introducing irritant or odorous material, other than that provided for in the Gas (Carbon Monoxide) Order of 1922, was considered by the committee on deaths from gas poisoning in 1930, but after reviewing the objections to such addition, the committee decided to make no recommendation in this respect. In accordance with another recommendation, a central advising committee was set up by the industries concerned, and he was satisfied that this committee would acquaint him with any development which would render further action practicable.

Blood Test Admissible as Evidence

Replying to Sir F. Fremantle, on April 24th, Sir JOHN GILMOUR said he was advised that if evidence with regard to a blood test in cases of disputed paternity was available it was admissible under the existing law in this country. Such difficulties as existed appeared to be rather of a practical than of a legal character, and to arise from the fact that the cost of arranging for such a test would fall on the man concerned, and that he would have to secure the co-operation of the woman. He was giving his careful consideration to the whole matter, but if there were any question of compelling persons to submit to a blood test legislation would be required for that purpose. Sir F. FREMANTLE asked if it would be possible for the Home Office to make the fact known to the magistrates of the country, that they might accept this evidence which at present they were refusing. Sir J. GILMOUR: I think there is no question that the magistrates are fully aware of that point. Sir F. FREMANTLE asked whether in cases where magistrates had refused such evidence, it would be possible for the case to be reopened. Sir J. GILMOUR: No, Sir. It would be for the magistrates to sum up what was the value of such evidence.

Examination by R.M.O. and Insurance Benefit

On April 24th Mr. CROOKE asked the Minister of Health if he was aware that certain approved societies refused health insurance benefits to members, although certified by their panel doctors, unless and until the applicants had been examined by the regional medical officer, and whether, seeing that that action caused unnecessary hardship, he would take steps to revise the rules of approved societies to ensure that payments of benefit were made before the members were sent to the regional medical officer. Mr. SHAKESPEARE replied that, when an approved society desired to obtain a second medical opinion on the subject of a member's incapacity for work, it was entitled to refer the case to a regional medical officer, and it was the general practice of societies in such cases to

APRIL 28, 1934]

MEDICAL NOTES IN PARLIAMENT

THE BRITISH MEDICAL JOURNAL 783

pay benefit in respect of any period of certified incapacity up to and including the date on which the member was examined by that officer. The payment was made at as early a date as accorded with the society's general administrative arrangements, and the Minister of Health did not think that it would be reasonable or practicable to impose on societies an obligation to make the payment in all cases before the date of the examination. Mr. MACQUISTEN asked if it was not notorious that panel practitioners were more facile than others in granting certificates in competition for patients. No answer was given.

Road Accidents During Easter.—Replying to Sir William Brass on April 18th, Mr. STANLEY announced that during the two weeks ended respectively April 15th and April 22nd, 1933, which included Eastertide, a total of 248 persons were killed or fatally injured in road accidents. Comparable figures were not available for the two weeks ended respectively March 31st and April 7th, 1934, which included Eastertide, as in many cases death from injuries did not take place until after the close of the week in which the accident occurred. It was, however, known that 187 persons were killed in road accidents during the two weeks in question. Past experience of the number of injuries which proved fatal after the close of the week in which they occurred indicated that at least sixty deaths would be added to the above figures. He regretted that fatal road accidents during the two Easter weeks of this year were likely to have been at least as numerous as during the two Easter weeks of last year.

Estimated Costs of Slum Clearance.—Replying to Mr. Craven-Ellis on April 19th, Mr. SHAKESPEARE stated that it was estimated that the annual charge to the Exchequer and local authorities when the programmes of slum clearance schemes so far submitted had been carried into effect would be about £3,100,000 and £1,070,000 respectively. It was not yet possible to furnish an estimate of the annual charge in connexion with the proposed scheme for the relief of overcrowding. These charges would remain a liability upon the Exchequer up to a maximum period of sixty years from the date of completion of the houses subject to some variation: (1) when loans were repaid under the Act of 1919, and (2) when subsidy ceased at the end of twenty years in the case of the Act of 1923, and at the end of forty years in the case of the Acts of 1924 and 1930. The liability on the local rates would continue with some variation for substantially the same period.

Derelict Areas.—Sir HENRY BETTERTON announced on April 19th that the Government had decided, before proceeding further with the special problem presented by the derelict areas, to have inquiries made in typical places within the districts of Durham, South Wales, Cumberland, and Scotland. Mr. J. C. C. Davidson would make investigations in Cumberland, Captain Euan Wallace in Durham and Tyneside, and Sir Wyndham Portal in South Wales. The Scottish investigator would be announced later.

Poor Relief.—Mr. SHAKESPEARE told Mr. T. Smith on April 19th that the total numbers of persons (men, women, and children) in receipt of poor relief in England and Wales (excluding rate-aided patients in mental hospitals, persons in receipt of domiciliary medical relief only, and casuals) on March 24th, 1934, and on the corresponding days in 1933, 1932, and 1931 were 1,413,780, 1,357,236, 1,188,077, and 1,038,432 respectively.

Health Insurance on Leaving School.—Replying to Mr. Rhys Davies on April 19th, Mr. SHAKESPEARE said careful consideration would be given to the suggestion that young persons, on entering employment after leaving school, should be brought within the scope of national health insurance as the case of young persons under the provisions of the Unemployment Bill now before Parliament. Financial difficulties made it impracticable to adopt the proposal at the present time.

Anaphylaxis in Diphtheria Immunization.—On April 23rd, in reply to Mr. Groves, Sir HILTON YOUNG said that his attention had been called to cases of anaphylaxis due to the infection of toxin-antitoxin. Anaphylaxis was not a phenomenon peculiar to diphtheria immunization. The relevant facts were widely recognized, and he did not consider it necessary to take any special action in the matter.

Recruitment to Indian Medical Service.—On April 23rd Sir SAMUEL HOARE informed Dr. John Williams that the resolution of the Council of State of India that recruitment to the Indian Medical Services should be by simultaneous competitive examination in Britain and India was withdrawn after the Government spokesman had given reasons why the Government of India could not accept it, and after an undertaking had been given that the debate would be forwarded to him. He had not yet received any observations from the Government of India on the matter. Sir SAMUEL HOARE also told Dr. Williams that according to information available on March 1st the actual strength of the Indian Medical Service was 385 British officers and 240 Indian officers; twenty-nine of the latter held temporary commissions.

Methylated Spirit Drinking.—On April 24th Mr. SKELTON told Miss Horsburgh that during the last six months representations in favour of legislation to prohibit or prevent the sale of methylated spirit or kindred spirits for human consumption had been made to the Secretary of State for Scotland on behalf of the town councils of Aberdeen, Clydebank, Dundee, Edinburgh, Falkirk, Glasgow, Greenock, Inverness, Paisley, and Stirling. As from March 15th, 1934, new formulae for surgical spirit had been brought into operation by the Commissioners of Customs and Excise. It was hoped that these would render surgical spirit undrinkable, and it was proposed to await the results of this experiment before considering whether further measures restricting the sale of methylated and surgical spirits were necessary.

Milk Supplied to Military Hospitals.—Mr. DUFF COOPER, replying to Lieut.-Colonel Heneage on April 24th, said that tenders were invited for fresh and for pasteurized milk for military hospitals, but not for "Certified" or Grade A milk. The fresh milk had to comply with the Department's specification, and was required to be not below the standard required by the Sale of Milk Regulations, 1901. Unless the cost was excessive, preference was invariably given to pasteurized milk, and this milk was being supplied to the majority of military hospitals under the existing contracts.

Notes in Brief

The Registration of Births, Deaths and Marriages (Scotland) Bill, which has passed the Commons, was read a first time in the House of Lords on April 24th.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Vice-Chancellor gives notice that the appointments committee of the Faculty of Biology "B" will shortly proceed to elect a university demonstrator in the Department of Biochemistry. Application should be made to Professor Sir F. G. Hopkins, from whom further particulars may be obtained, before May 2nd.

A course of eight lectures will be delivered during the present term by Dr. Walter Pagel of Heidelberg on the history of biology and pathology, entitled "Theories of Life and Disease." They will take place on Tuesdays and Fridays at 4.30 p.m. in the lecture room of the School of Biochemistry.

The Linacre Lecture will be delivered by Sir Henry Dale, M.D., F.R.C.P., Sec.R.S., director of the National Institute for Medical Research, on Saturday, May 5th, at 5 p.m., in the lecture room of physiology, New Museums. The title of the lecture is "Chemical Transmission of the Effects of Nerve Impulses."

UNIVERSITY OF LONDON

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

The following candidates have been approved at the examinations indicated:

DIPLOMA IN PUBLIC HEALTH.—Part I: O. M. T. Ansari, W. H. Crichton, F. R. Dennison, H. A. Dirchze, Margaret L. Foxwell, Muriel O. Gibson, G. S. C. de S. Ganesekera, Ellen G. Heycock, F. E. Lipscomb, F. J. G. Lishman, G. H. Lowe, G. P. McC. Marshall, K. J. G. Milne, D. D. Payne, Ethel A. Perrott, C. D. Preston, Alison J. Rae, L. Roberts, L. B. E. Seneviratne, Mary Sutcliffe, L. G. W. Ulrich, S. L. Wright.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—With Special Knowledge of Psychiatry: Winifred M. Burbury, A. B. Carter, B. Cates,

M. S. Jones, W. G. Rees. *With Special Knowledge of Mental Deficiency*: R. M. Bates. *Part A*: R. W. Maxwell, Grace H. Thomson, W. P. Berrington, N. McDiarmid, W. E. McIlroy, D. Prentice.

UNIVERSITY OF GLASGOW

A graduation ceremony was held on April 21st, when the following degrees, among others, were conferred:

M.D.—F. M. Christie, H. Fairbairn (*in absentia*), J. J. Flind, J. S. I. A. Laidlaw, J. P. Shannon, A. Duff, G. G. Macpherson, N. McE. Montgomery, A. Ogg, T. Paton, H. S. Russell, A. G. Smith, Jean W. Symington, R. N. Walker.
M.B., Ch.B.—E. W. Walls, J. A. Muir, I. M. Anderson, C. Arak, A. Cameron, D. Campbell, J. Campbell, W. Clark, J. M. Cook, R. G. H. Cunningham, Elizabeth M. Deighton, J. C. Fitch, C. M. Fraser, W. Gibson, J. Gilmore, W. Guthrie, Jean A. Holburn, A. S. Hutcheson, A. B. Kinnick, J. Kelly, S. M. Laird, C. M. Lamont, Jean H. McL. Laurie, Magdalene Linton, S. Loman, A. McS. MacArthur, A. D. MacArthur, K. MacColl, Jennie J. Macdonald, Maud P. MacDougall, S. W. MacDougall, D. Macfarlane, P. A. McE. Macgregor, J. Mackenzie, M. J. McLaughlin, W. B. McLean, J. McPheat, T. J. R. Miller, N. Morrison, W. W. Muir, J. Murray, S. S. Naftulin, J. S. Norwell, G. A. F. Quinnett, H. J. Reid, Jessie V. M. Robb, W. Rodger, R. L. Roxburgh, J. B. Shiel, E. I. Smith, Margaret B. Strel, J. N. R. Stephen, J. W. Strachan, J. C. Taylor, R. B. Taylor, Kathleen M. Warren, H. Weir, G. Witherspoon, D. D. Young, B. Zahn.

* With high commendation. † With commendation.
‡ With honours.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY—A. E. Ginn, C. W. Hardy, R. G. Joyce, H. Murkus, D. Roeyn-Jones.

Medicine—S. Grodd, H. G. Howitt, L. A. Lewis, T. Morgan, F. D. Paterson, J. H. Playne, P. H. Wilcox.

FORENSIC MEDICINE—P. T. M. Clarke, S. Grodd, B. S. Menden, J. R. Owen, F. D. Paterson.

MIDWIFERY—J. A. Carter, S. Klein, J. E. T. Muir, C. W. O'Donoghue, F. D. Paterson, D. Walton, J. P. Walsh Conway.

The diploma of the society has been granted to S. Grodd, T. Morgan, P. D. Paterson, J. H. Playne, J. P. Walsh Conway, and P. H. Wilcox.

Medical News

The annual dinner of the Cambridge Graduates' Medical Club will be held at the Langham Hotel, W., on Wednesday, May 9th, at 7.15 for 7.45 p.m., with the president, Dr. H. Morley Fletcher, in the chair. The honorary secretaries are Dr. E. G. Chandler and Mr. W. D. Doherty.

The annual spring dinner of the Queen's University Club, London, will be held at the Dorchester Hotel, Park Lane, W., on Thursday, May 3rd, at 7.30 p.m. Professor Hinny will preside. Members may obtain tickets from the honorary secretaries, 101, Harley Street, W.1.

The lecture on "The Skin in Relation to Rheumatism in Childhood and after Puberty," arranged to be delivered by the late Dr. L. J. Llewellyn on Thursday, May 3rd, at 4 p.m., at the Medical Society of London, 11, Chandos Street, W., will be read from the manuscript prepared by Dr. Llewellyn, by Dr. D. F. Fraser-Harris.

The Royal Sanitary Institute has arranged a sessional meeting at the Guildhall, Portsmouth, on Friday, May 11th, at 4.45 p.m., when there will be discussions on "The Housing and Slum Clearance Problem in Portsmouth," to be opened by Councillor A. E. Allaway, and on "Naval Hygiene," to be opened by Surgeon Commander H. St. C. Colson, Naval Health Officer for the Portsmouth Command.

The Hospital for Sick Children, Great Ormond Street, W.C.1, announces that a few vacancies exist for clinical assistants to the physicians to out-patients. Applications from practitioners registered in this country who are willing to give their services for a few hours on one or two mornings each week should be sent to the secretary. A post-graduate course on diseases of children will be held at the hospital from April 30th to May 12th, from 10 a.m. to 1 p.m., and from 2 p.m. to 4 p.m. daily, except Saturdays (10 a.m. to 1 p.m.). The fee is £6 6s.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that Dr. Clark-Kennedy will lecture on auricular fibrillation at 11, Chandos Street, on Tuesday, May 1st, at 2.30 p.m. The sixteenth lecture on digitalis will take place on Tuesday, May 8th. There will be a week-end course in cardiology at the City of London Hospital, Victoria Park, on May 5th and 6th, occupying the whole of both days, and including lectures, demonstrations, and films. There will be a fortnight's course in advanced urology at St. Peter's Hospital, May 7th to 19th; and a demonstration of cases by Dr. H. L. Marriott, dealing with blood diseases, at the National Temperance Hospital on Saturday, May 12th, at 3 p.m. For post-graduates who cannot find time to attend a special course, covering a period of two to four weeks, individual clinics in various branches of medicine and surgery are available daily by arrangement with the Fellowship of Medicine.

The Central Association for Mental Welfare has arranged a course for officers of local authorities and local associations for mental welfare engaged in the ascertainment and supervision of defectives; and another course for persons engaged in the training of mental defectives in occupational centres, institutions, or mental hospitals. Both courses will be held in London from June 30th to July 21st. A syllabus and time-table will be sent to all students a week before the opening day of the course. Copies of the circulars, forms of application, and any further information may be obtained from the secretary, Central Association for Mental Welfare, 24, Buckingham Palace Road, S.W.1.

The German Society for Psychiatry will hold its annual meeting at Münster in Westphalia from May 23rd to 25th, when the following subjects will be discussed: clinical psychiatry and eugenics, introduced by Professor Bumke of Munich; encephalography in psychiatry and cerebral pathology, introduced by Professor Jacobi of Magdeburg; personality in psychotherapy, introduced by Professor Kretschmer of Marburg; and psychiatry and racial hygiene, introduced by Professor Rudin of Munich.

We are informed that the appeal on behalf of the fund to raise a memorial to Dr. Henry T. Hodgkin, of whom an obituary notice appeared in the *Journal* of April 1st, 1933, has met with a gratifying response. The sum already contributed amounts to £1,900, and the Executive Committee has decided to close the fund on June 23rd next. The Bishop of Croydon and Mr. Harold Morland have been asked to present the money to the governors of the West China Union University, at their annual meeting to be held at Oxford on June 25th and 26th. Cheques should be made payable to Mr. Harold J. Morland, 2, Eaton Gate, S.W.1.

The number of blind persons in Italy, according to the latest statistics, is about 25,000, as compared with 28,357 in 1911. The population of Italy, however, in 1911 was 34,000,000, as compared with 42,000,000 to-day, so that formerly the proportion of blind persons was 81 per 100,000, while now it is only 60.

The Minister of Health has appointed Mr. J. A. Lawther as secretary to the Departmental Committee on the Cost of Hospital and other Public Buildings, and all communications relating to the work of the committee should be addressed to him, at 2, Whitehall Gardens, S.W.1.

Professor Haven Emerson, M.D., of New York has been elected an Honorary Fellow of the Royal Sanitary Institute.

The King has confirmed the appointment of Major T. J. Hallinan, C.B.E., to be a nominated member of the Legislative Council of the Island of Jamaica.

The following have recently been elected members of the Académie de Médecine: Foreign corresponding members—Dr. Blanco Acevedo, professor of clinical surgery at Monte Video, and Dr. Constantin Daniel, professor of clinical gynaecology at Bucarest; national corresponding members—Dr. Paviot, professor of clinical medicine at Lyons, Dr. Halipré, director of the medical school at Rouen, Dr. Bridié of Algiers, and Dr. Veh of Casablanca.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

An Unusual Sign in Diabetes Mellitus

Dr. R. E. M. FAWCETT (Cirencester) writes: The following case is, I think, of sufficient interest to merit publication. A middle-aged man noticed that a white powdery substance kept appearing on the sides of his shoes; this happened in successive pairs of shoes after he had worn them a very short time. Thinking that there was some fault in the preparation of the leather, he returned a pair to the makers. The firm, which is a very well known one, sent the shoes to their analytical chemist, who reported that the substance was sugar, and suggested that the wearer worked with sugar; he is, however, a tailor by trade. He was worried by this report, and came for advice. He gave a history of indifferent sleep, and slight, but definite, loss of weight. On examination of the urine it was found by Benedict's method to be loaded with sugar, and subsequent investigation has established the case as one of diabetes mellitus of moderate severity. The method by which the diagnosis was arrived at is, I think, of interest, and I would be glad to know if such a condition is of at all frequent occurrence in diabetics.

Women's Shoes

"PEDIPUS" writes from Yorkshire: What can ladies do to prevent the bunions, corns, etc., which we so frequently see? Fashion demands that the shoe should be so narrow that the foot is crushed into it without complaint until the bunion arrives. Ladies' dress is years ahead in comfort and hygiene of that of the opposite sex, and yet they still tolerate the fashionable shoe. High heels no doubt improve the appearance of the calf and ankle, but why crush the foot sideways?

A Sudden Toupee

"G. M. R." writes: A lady aged 50 who wears a toupee through partial loss of hair complains that it deteriorates rapidly. This, the coiffeur says, is due to "acid sweat." Can any reader kindly suggest a remedy?

Mate Leaves for Rheumatism

"INQUIRER" writes: The leaves of *mate*—a Paraguay plant—have been vaunted as a specific for rheumatism. Is there any evidence that the taking of the infusion of these leaves has been beneficial?

Chronic Gonococcal Infection

"M. S." writes from Burma in reply to "Perplexed's" inquiry (February 24th, p. 363): I would suggest passage of both anterior and posterior urethral sounds on alternate weeks, and light massage over the same. The patient should have two to three doses of manganese butyrate to start with, once in three to seven days, depending on the reaction, and then a course of mixed detoxicated vaccines (stock), giving large doses, and a series of sterile milk injections (2 to 5 c.c.m. for each dose), given intra-

muscularly. Orally, hexamine and sodium benzoate, in mixture, can be alternated with other milder antiseptics, like pyridium and acriflavine. As it is a very chronic infection, if irrigations are used at all, only the mildest should be used, and those infrequently. Such drugs as acriflavine and potassium permanganate, with an occasional irrigation with silver nitrate. I am assuming that "Perplexed" has not got a diathermy apparatus.

Income Tax

Car Transactions

"W. B. S." bought a second-hand "S" car for £52 10s. on June 13th, 1933, and sold it for £28 10s. on November 6th, 1933, buying a new "F" car on the same date for £126 10s. Should he claim depreciation or renewals?

* * The inspector of taxes calculates the allowance as follows:

Depreciation: "S" car, 15 per cent. of £52 10s.	
for twenty-one weeks	£3 3 7
"F" car, 15 per cent. of £126 10s.	
for twenty-one weeks	£7 13 1
Say	£11 0 0

Obsolescence: £52 10s. - (£3 depreciation allowed and £28 10s. received for sale =) £31 10s. net £21.

Those allowances are the best obtainable. If cost of renewal were claimed the amount due would be £52 10s. - £28 10s. = £24, and the "dépréciation" claim would be excluded.

Car Used but No Car Allowance Received

"ASST. T.O." is required to do visiting as part of his work, but receives no allowance other than bus fares. He bought a car in July, 1933, and uses it about equally for work and pleasure. How should he proceed to obtain an allowance for income tax of his current expenditure?

* * As "Asst. T.O." holds an office of employment his assessment is governed by the rules of Schedule E, and he will be required to show that the car expenditure is incurred "necessarily" in the performance of the duties of his office—that is, in making his visits, not in travelling to and from his residence. As the employing authority apparently considers that bus fares are adequate payments, he will probably have some difficulty in satisfying the tax authorities that the car expense is "necessary." However, he had better launch the claim by showing a specific deduction in his return for the current year on the basis of a reasonable proportion of his running expenditure between July, 1933, and April, 1934, and in due course explain the position fully if it should become necessary.

Basis of Assessment—Assistant

"D. P. H." earned £250 during the year 1933-4 by working as a locumtenent. For all the year 1934-5 he is employed as an assistant M.O.H., at a salary of £500. On which income will his allotment for 1934-5 be based?

* * On the £500; as holding the specific appointment of M.O.H. he is assessable under Schedule E, whereas his former earnings fell under Schedule D, and the change necessitates a fresh start, which results in assessment on the current year's earnings for 1934-5.

Expense Incurred by Assistant

"D. H." is engaged as an outdoor assistant, receiving a salary plus car allowance at £1 per week. He has had to take a special house belonging to his chief at a rental of 25s. per week inclusive. Can he deduct (a) part of rent, wages of maid, etc., and (b) the excess of his actual car running cost over the allowance?

* * (a) Yes; so far as the expenses are really increased by the professional work—in the circumstances probably quite a small amount. (b) Yes; provided all the cost arising out of private use is excluded.

Purchase of Practice and Debts—Basis of Assessment

"S. P. G." has bought out his partner, and has paid him his share of the outstanding bills; the money outstanding is now coming in. Is he liable for tax on those receipts as income?

* * The receipts from his former partner's share of the outstanding debts are not "income" to "S. P. G."—he bought them, and to him they represent a return of capital. On the other hand, he is now liable for the full earnings of the practice, and for the first year or two of his sole proprietorship of the practice the Revenue authorities will

not be content to accept as the gross income of the whole the cash received from only a part of the practice. They will be entitled to require "S. P. G." to depart from the cash basis and adopt the "earnings" or "book debts" basis for the future; or, as an alternative, may be willing to accept the cash basis on condition that the whole of the receipts are brought into the computation, even though a part may represent capital and not income so far as he is concerned.

"Child Allowance"

"A. B." has a son 22 years of age who is taking a postal correspondence course for an accountancy examination—working on it at home the whole of his time. Can "A. B." claim the allowance for this financial year?

** The matter is governed by Section 21 of the Finance Act, 1920, and the relative requirement is that the child "is receiving full-time instruction at any university, college, school, or other educational establishment." We do not know of any judicial decision on the matter, but in our opinion a vocational postal course of tuition would not provide sufficient ground for a claim.

LETTERS, NOTES, ETC.

Barbiturate Poisoning

Messrs. MAY AND BAKER LIMITED, manufacturing chemists, Dagenham, London, write: Our attention has been drawn to the letter by Dr. Stafford Geddes with this heading in your issue of April 14th (p. 689), dealing with the cumulative effect of the barbituric group of drugs. We must confess that it does not appear to us that the case described affords any proof of the cumulative effect of the drugs referred to. The dosage of sodium soneryl should be based on the weight of the patient, and it would be interesting to know what the weight of the patient was. The patient was "apparently" in good health, but it is not evident that any subsequent examination was made to establish whether this really was the case. We know of only one death caused by soneryl, and that in the case of a lady whose general state of health was such that she should definitely not have taken a hypnotic of any description. She actually took a very large overdose. We do, however, know of cases where up to 100 tablets of soneryl have been taken, and the patient recovered. In one instance 1,500 grains were taken in a month. We maintain that soneryl is the least toxic of all barbituric acid derivatives, and a perfectly safe drug when administration is carefully controlled by a medical man.

Handy-women and Puerperal Sepsis

"Q. Q." writes: There is one factor which is persistently ignored in these discussions, and that is the problem of the untrained nurse. Practitioners are not supposed to attend maternity cases with untrained persons, but they do so in scores of cases, and I have to also. In these times of poverty, even if maternity benefit is available, there is not sufficient to pay both a doctor and a trained nurse, and hence the poor patient and the doctor have no choice. The remedy is not easy, but I suggest that the local public assistance committees take these cases on their merits and grant assistance, provided, of course, that the practice of these women was declared illegal. A few of these women are trustworthy, but many are not, and I have refused to attend cases with some, with the risk of the loss of the patients and much unpleasantness. Numerous examples of their irregularities can be given, which the medical officers of health and practitioners are up against. While attending a normal case an untrained person may have been in contact with a puerperal case or an abortion, and may be doing all kinds of nursing in the neighbourhood, septic or otherwise, which the attending doctor may know nothing about. Recently I had to report a woman to the M.O.H. here for doing vaginal examinations, without any precautions, before my arrival at a case! Surely this is a direction in which improvement could be made?

The Young Idea on Health

Over 25,000 children in elementary schools in Great Britain and Northern Ireland sat down one day in October last to answer five questions on how best to avoid disease. The best answers from each school, 582 in all, were sent up to the Empire Health Week Committee of the Royal Sanitary Institute for adjudication, and the assessors have now made their award, which is signed by Dr. George F. Buchan as chairman of council. A medal will be presented to each of the winners, while the successful schools will hold the two challenge shields for a year. Begun on a

modest scale in 1912, Health Week is now firmly established. It is celebrated annually in hundreds of centres in the United Kingdom, and in many cities and towns in India, the overseas Dominions, and the Colonies. The King and Queen have honoured the movement with their patronage. Many of the papers sent in for the competition reached a high standard, showing a grasp of the subject which does credit to their teaching. Some of the answers are unconventional: one boy was asked to describe the spine. "The spine," he said, "is a bundle of bones which runs up and down the back and holds the ribs together. The skull sits on one end and I sit on the other."

Treatment of Bilharzia Disease

Dr. F. G. Cawston (Durban) writes: The discovery of specifics has fostered the impression that parasites may be destroyed by a sufficiently large dose of a drug, even though its value is sometimes greatly enhanced by the addition of other drugs and by the use of vaccines. If antimony alone were responsible for the death of schistosomes a remedy would depend entirely on its antimony content, and the required dose of tartar emetic would cure a case of bilharzia disease in less than a month. Success depends rather on certain changes which are gradually brought about in the blood of patients whilst under the influence of antimony, which, in therapeutic doses, is an excellent hepatic stimulant. These changes are hindered by anything which upsets the general health, and attempts at the rapid destruction of these large blood parasites may even be dangerous. The changes in the constitution of the blood are indicated by the response to the complement-fixation test and by the eosinophil count. These changes help to explain why recent infections with a high eosinophilia are more difficult to cure than chronic infections. Toxic effects may cause the temporary disappearance of escaping ova. The final test of cure is evidenced by their permanent absence from both urine and faeces, by the return to normal of the eosinophil count six to eight weeks after treatment has been discontinued, and by the general improvement of the health. Evidence to show that the male parasites are dead has always been omitted from records of alleged cures where treatment has been continued for less than four weeks. Tartar emetic has been shown to effect a true cure when skillfully administered over a period of one month. Other preparations usually require to be given in two distinct courses before both male and female parasites are destroyed.

Allotments for the Unemployed

The Allotments Committee (Friends House, Euston Road, N.W.1) announces that it has accumulated a fund out of which it can offer seeds, potatoes, tools, and fertilisers at greatly reduced prices for unemployed men and women, those who are recovering from a bout of unemployment, and others who are seriously impoverished. Help has already been given to 100,000 unemployed men, and it is hoped to increase this number considerably during the current year. Information about the obtaining of allotments is available at the offices of town clerks, labour exchanges, or from the Allotments Committee. Details of the scheme can also be obtained from Friends House (Form H). It is added that cultivation of an allotment does not affect a claim for unemployment benefit.

"The Open Door"

Under the title "The Open Door" Dr. Barnardo's Homes, 18-26, Stepney Causeway, E.1, have issued an illustrated booklet showing how orphan and destitute boys and girls are rescued from pitiful surroundings, given a new environment, and trained for ways of useful citizenship. This title is apt, because under the charter no destitute child is ever refused admission. In 1932 alone 1,735 destitute children passed through the open door, and more than 1,500 young people, trained and equipped, passed out into the world. The family supported by Dr. Barnardo's Homes now numbers 8,478 boys and girls and babies; and on an average five newcomers join it every day. In all, 114,102 children have been admitted.

The photograph of Dr. David Lees reproduced with our obituary notice on April 7th was taken by Mr. Andrew H. Baird, scientific instrument maker, of Edinburgh.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 39, 40, 41, 42, 43, and 46 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 236.

STRANGULATED HERNIA

ITS PREVENTION AND TREATMENT UNDER LOCAL AND OTHER ANAESTHETICS

BY

R. WOOD POWER, M.B., F.R.C.S.I.

SURGEON, HEREFORD GENERAL HOSPITAL

The object of this paper is to record the results obtained by operation upon strangulated hernia under local and other anaesthetics. I have noticed that under the former the patients have less post-operative shock, their condition gives rise to less anxiety, and their eventual recovery is less hazardous and more rapid. I have come to the conclusion that it is the anaesthetic *par excellence* for this condition, and that it should invariably be employed. In discussing such vast subjects as toxæmia, pulmonary complications, and shock, I have only considered them from the anaesthetic point of view. Finally, I have endeavoured to show how strangulated hernia should become a tragedy of the past.

The treatment of strangulated hernia within recent years has been very scantily reviewed and too infrequently discussed. At the Centenary Meeting of the British Medical Association, when the subject of intestinal obstruction was debated by the Section of Surgery, one was struck by the absence of any special reference to strangulated hernia. This is all the more to be wondered at if one refers to the admirable statistics prepared by Vick¹ for that discussion; nearly half the cases (3,267 out of 6,892) of intestinal obstruction were due to strangulated or obstructed hernias. The importance of this subject may be judged from the fact that each year in England and Wales, according to the Registrar-General's returns, over 2,000 people die from strangulated hernia. If one takes Vick's mortality rate of 18 per cent., then over 11,000 operations are performed yearly upon this condition.

I do not intend to give detailed statistics of the various types and complications of strangulated hernia. Anyone requiring such information should read Frankau's² excellent paper, in which he has reviewed 1,487 cases from the various London hospitals. I find that my figures, though small, compare favourably with his.

The care of a patient with a strangulated hernia may be broadly divided into two stages: first, when he is in the hands of his own doctor, and secondly, when the surgeon takes charge. It was customary among surgeons at one time to throw the blame for the death of these patients upon the general practitioner. This day has rightly gone, and Sir Henry Newland³ further emphasized this point when he said:

"It is all very well for surgeons with one accord to excuse themselves, and to assert that the responsibility for that death-dealing delay is not theirs. The fact remains that acute intestinal obstruction is a surgical condition. It is to the surgeons attached to the medical schools throughout the Empire that the profession looks for light and learning."

I can only recollect two cases where the diagnosis was missed by the doctor in charge: in the first there was a small femoral hernia in a young girl, who unfortunately had a gangrenous bowel by the time the operation was performed, and died the following day, and in the second no examination was made, but luckily the patient recovered.

THE QUESTION OF TAXIS

When the general practitioner is called to a case there are two lines of treatment open to him, the first of which is taxis. Taxis should only be attempted in the early stages of strangulation, and should always be gentle. It

is impossible to lay down a definite time limit after which taxis is dangerous; it entirely depends upon the degree of strangulation. If I were pressed to state such a time limit, I would say that it was unwise to attempt this form of reduction if the strangulation had existed for more than four or five hours. The general practitioner, as a rule, has a limited experience in dealing with such cases; it is far safer to leave the attempt to the surgeon, who is generally better fitted to judge whether taxis is advisable or not. To effect a reduction *en masse* in a hospital where an immediate operation can be carried out is dangerous enough, but to attempt reduction in the patient's home, perhaps many miles from a hospital, may result in a catastrophe causing death.

When attempting taxis I have found it useless to grasp the fundus of the hernia and apply pressure at this point; it only causes further distension and congestion of the neck of the sac—the very place where relaxation is required. The reasoning of this must be apparent to all surgeons who use the gridiron incision for appendicectomy. In those cases in which it is necessary to deliver the whole caecum out of the wound for the removal of a high retro-caecal appendix, we have all experienced the difficulty at times of returning the bowel to the abdomen, and we all know how futile it is to grasp the caecum at its most dependent part and attempt to reduce it; such a procedure is never successful, and must cause damage to the bowel. The correct method is to replace it in the reverse order from which it was extracted—that is, the part lying between the edges of the wound is first returned to the abdomen, and as each succeeding portion of the intestine enters the wound it is replaced in the same manner. A strangulated hernia is an exactly similar condition, and if we hope to reduce it we must act on the same basis. The best method of taxis is to apply pressure at the neck of the sac or as near it as possible; direct pressure at this point will contract the neck of the sac and, if the constriction is not too firm, reduction may take place and the remaining bowel follow quite easily. This may be feasible in an early case of inguinal hernia, especially if the thigh is flexed and internally rotated to relax the pillars of the ring, but it is quite impossible in a femoral hernia. In the latter, taxis should on no account be attempted either by the general practitioner or by the surgeon. It is quite impossible to reach the neck of the sac, and any attempt at reduction will only damage the bowel further and possibly cause a rupture. I have never known a femoral hernia reduced by taxis, and any attempt to do so should be looked upon as dangerous practice. The same remarks apply to umbilical hernias in stout people: it is impossible to reach the neck of the sac, and so reduction is impracticable.

Should taxis fail, or if it has been deemed inadvisable, there is a second line of treatment open to the doctor on the spot—that is, to raise the end of the bed. This allows the distended bowel to fall away from the hernial opening, and must, I think, reduce the pressure at this point; in addition, it has a traction tendency. I have known several cases reduce themselves by this method, especially if morphine has been administered. It should never be used as an alternative to operation unless such has been refused, but may be employed while preparations are being made for the removal of the patient.

When the surgeon takes charge of the case the question of mortality at once presents itself, and may be considered under four heads: the social status of the patient, toxæmia, pulmonary complications, and shock.

SOCIAL STATUS OF THE PATIENT

The social status of the patient appears to be one of the chief factors in connexion with the mortality of strangulated hernia. By this I mean that the hospital class of patient seldom sends for his doctor until the case is far advanced, whereas the well-to-do patient will not tolerate the pain and discomfort for anything like the same length of time. There can be no doubt that if all cases of strangulated hernia were operated upon within the first few hours, the mortality would be extremely small. The present high mortality is very largely due to delay in operating. This delay is more marked in rural districts, where distance, conveyance, and the scarcity of doctors have all to be taken into account.

In considering the immediate causes of death—namely, toxæmia, pulmonary complications, and shock—the question arises: How are we to minimize these complications? This point presented itself to me some years ago, and since then I have been working methodically in an attempt to reduce the mortality. I have observed that many patients who die never appear to rally from the operation, and I have come to the conclusion that if these cases were operated upon under local anaesthesia they would stand a far greater chance of recovery.

TOXAEMIA

Everyone is aware of the early and extreme toxæmia associated with intestinal obstruction. If a small portion of the liver be removed at an operation for intestinal obstruction and sectioned it will be found that the cells show cloudy swelling. If a similar section is made from the liver of a patient who has died from intestinal obstruction it will be difficult to recognize the liver cells at all. The venous return from the intestine passes by way of the portal vein to the liver, and permeates the liver cells. This blood contains highly virulent toxins, and accounts for the condition of the liver cells just described. To put any further strain on the liver cells must lessen the chance of recovery, and by administering chloroform, or a mixture of chloroform and ether, we are undoubtedly doing this, for chloroform is poisonous to the liver and in advanced cases causes necrosis of its cells. Chloroform, then, should on no account be used in operations for strangulated hernia, and Frankau's figures show the highest mortality from this anaesthetic. I am quite convinced that it makes the difference in many cases between life and death.

PULMONARY COMPLICATIONS

It is well known that many of these patients are chronic bronchitics, and that the hernia is gradually enlarged by constant coughing. To administer ether in these cases is to run a very grave risk of setting up pulmonary complications, for such patients are usually aged and infirm, and readily show signs of pulmonary congestion. One of the frequent causes of pulmonary involvement is the inhalation of highly infective material from the stomach, either during the induction of the anaesthesia or following the operation. The chances of this can be greatly reduced by careful lavage of the stomach both before and after operation. The stomach in cases of intestinal obstruction and peritonitis can be compared to a bladder with overflow retention, for as a rule vomiting does not occur until the stomach becomes full. What is vomited is usually of an overflow nature; this can be verified by passing

a stomach tube after a patient has vomited, when large quantities can be drawn off. This overflow retention must be regarded in the same serious light as retention of urine in the bladder; in the latter condition we get back pressure on the kidneys and the consequent amassing of poisonous substances in the blood, while in the former we get toxins of a very lethal nature remaining in the system, if the stomach is not kept empty to receive them. Nothing brings more comfort to vomiting patients than a gastric lavage, after which they settle down to a slumber more restful than any drug can produce.

SHOCK

The fourth cause of death—shock—occurs in advanced cases. No one would consider anaesthetizing a patient suffering from shock following an accident unless it were imperative, yet here we have a patient on the very verge of this condition. It is little wonder that such patients never regain consciousness, and rapidly succumb after the operation. Spinal anaesthesia, as we know, causes a fall in blood pressure with resultant shock; this anaesthetic method is excellent when the abdomen has to be opened for intestinal obstruction, but people who suffer from strangulated hernia are often, as I have stated, aged and infirm, and it seems unreasonable to anaesthetize half the body, and so predispose them to shock, when a limited circumscribed area of anaesthesia is all that is required.

CAUSE OF DEATH

There have been fourteen deaths in seventy-eight of my cases, giving a mortality of 17.94 per cent. If reference is made to Table I the various causes of death will be found tabulated, together with the type of anaesthetic used in each case.

TABLE I

Cause of Death	No. of Cases	Anaesthetic Employed		
		Spinal	General (C. and E.)	Local
Toxaemia	8	2	4	2
Peritonitis	2	—	1	1
Pulmonary	1	—	1	—
Shock	3	1	2	—

Eight patients died from toxæmia—that is, they survived the immediate shock of the operation and succumbed within, as a rule, the next forty-eight hours. Two of these deaths occurred following spinal, four following general, and two following local anaesthesia. The degree of toxæmia depends on two factors: first, the time the strangulation has existed, and secondly, its intensity. If this condition were to continue there must come a time when any form of operation will fail to save the patient's life, but it is the period immediately preceding this stage that is the important one, and it is this period, I think, where the employment of local anaesthesia can make all the difference between life and death. Two patients died from peritonitis; they were very advanced cases, in which the bowel was found gangrenous at the operation. Such cases are usually hopeless, for a generalized peritonitis on the head of extreme toxæmia is more than the patients can endure. One patient who was operated upon under general anaesthesia died from pulmonary complications on the fifth day. Three patients died after the completion of the operation, and must be classified under shock. In one spinal anaesthesia was used; in the other two a general anaesthetic was given.

Table II shows the percentage mortality under each anaesthetic. The high mortality rate under spinal anaesthesia is accounted for by the fact that it was used in a small number of serious cases some years ago when stovaine was in vogue. I have often found this drug to cause an alarming fall in blood pressure, and it has now, I believe, been largely replaced by percaïne and tropacocaine. There were eight deaths in thirty-eight cases

TABLE II.—Mortality Rate under each Anaesthetic

	No. of Cases	No. of Deaths	Mortality Percentage
Spinal	6	3	50.0
General (C. and E.)...	33	8	21.05
Local	31	3	8.82

under general anaesthesia, giving a mortality of 21.05 per cent., and three deaths in thirty-four cases under local anaesthesia, giving a mortality of 8.82 per cent. The cases operated upon under local anaesthesia have been an uninterrupted series, so that all types and conditions are included. These figures are admittedly small, but still they are sufficiently suggestive to point to the fact that local anaesthesia is the ideal one for operations on cases of strangulated hernia.

OPERATIVE TECHNIQUE

On admission the patient is examined and taxis tried, if it be deemed advisable. Failing this the stomach is washed out until the fluid returns clear; the foot of the bed is then raised and the patient given 1/4 grain of morphine and 1/100 grain of hyoscine; the area for operation is shaved and the usual preparation of the skin carried out. I cannot speak too highly of the effect of twilight sleep, for by the time the patient is ready to go to the theatre he is invariably sound asleep, and can only be aroused with difficulty. These drugs are seen at their best in patients who have been in pain and without sleep for some time; these people have no recollection of going to the theatre or undergoing the operation. On several occasions I have been asked by them next morning when the operation was going to take place. I prefer these two drugs to the barbiturates; they are less toxic, simpler to administer, and more certain in their action. If one of the barbiturates is preferred, it should be given intravenously, since it is very doubtful if a secreting stomach has the power to absorb it.

When the patient reaches the operating theatre he is at once placed upon the table, and the area for operation infiltrated with 1 per cent. kerocaine. This drug is of British manufacture and extremely cheap; I have employed it in all my cases, and have found it as efficient as any other. It is non-toxic, and I have used as much as sixteen ounces at an operation without any ill effect. I infiltrate with Labot's syringe and needle; this needle is fine and long, and allows practically the whole area to be infiltrated through the one puncture. The needle is inserted about an inch and a half internal to the anterior superior spine; the deep tissues are first infiltrated around the hernial swelling, next the subcutaneous tissues, and finally the needle is reinserted at the top of the scrotum and passed up along the spermatic cord beneath the hernial sac to the internal ring, and this area infiltrated. This is a most important area to anaesthetize if the operation is to be painless, and it cannot be reached by a direct route. If this is not done there is bound to be pain when dealing with the peritoneum.

THE INGUINAL OPERATION

I do not wish to dwell on the technique of this operation, except to make a few remarks on the repair of the hernial opening. When the sac has been removed my procedure is to turn down a flap of fascia from the internal oblique and suture it to Poupart's ligament, which is scarified to receive it. These two raw areas of fascia unite firmly, and make a strong and lasting floor to the inguinal canal. It was my custom at one time to take strips of fascia from the thigh for this repair, but I now consider this unnecessary, except in rare instances. The graft from the internal oblique is a living one, and I have not yet experienced any ill effects from the use of it. In large hernias in elderly patients I remove the cord and testicle; this permits complete closure of the inguinal canal, and adds greater strength to the wound. In these cases, after the internal oblique fascia has been sutured to Poupart's ligament, the upper edge of the external oblique is sutured to the same position, the lower edge overlaps this, and is sutured down in completion of the operation. This operation provides a treble layer of fascia, and I have never seen a recurrence of the hernia. When it is completed the scrotum is raised and firmly bandaged to the pubis to prevent the occurrence of an haematoma.

THE FEMORAL OPERATION

In considering the femoral operation we have the choice of two approaches—namely, the inguinal or Lotheisen's, or the femoral, associated with the name of Lockwood. Of the two the inguinal route is the better, and is more frequently employed. The advantages of this operation are: (1) the constricted neck of the sac is easier to deal with; (2) a better inspection of the intestine can be carried out and a resection performed if necessary; (3) it allows better repair of the wound; and (4) there is less danger of wounding the bladder or an abnormal obturator artery. The real danger of the femoral operation is the possibility of the bowel slipping back into the abdomen before the sac is opened, and thus preventing a proper examination being carried out. Those who employ the femoral route claim that it is a quicker operation, and this is undoubtedly a fact, but I do not think the saving of a few minutes (especially when local anaesthesia is used) outweighs the advantages of the inguinal operation. I only perform this operation in early cases, when the necessity of a resection is unlikely and the patient a poor operative risk.

When repairing the hernial orifice I bring down a living graft from the internal oblique, as in the inguinal operation, and suture it to the pectineus fascia. I think this is a wise procedure, for Husted⁴ has reported 21 to 32 per cent. of recurrences following the operation of suturing Poupart's ligament to the pectineus fascia or the periosteum of the pubic bone.

Hey Groves has introduced a modification into Lotheisen's operation which is worthy of note. It consists in detaching Poupart's ligament from the pubic bone and turning it outwards, after which the sac can be lifted from its bed without any difficulty. I had a very striking example recently of the usefulness of this, when I came across a very inflamed and adherent sac of a femoral hernia, which turned out to contain a pus tube. To have attempted to deal with it in the ordinary manner would have caused considerable damage, and the probable rupture of the tube into the abdominal cavity. This modification is to be strongly recommended in those cases where one is led to expect some damage to the bowel, for even very gentle manipulation may cause a rupture of the intestine if it is damaged.

THE UMBILICAL OPERATION

The Mayo operation is the operation of choice in this type of hernia. After the sac has been removed and the peritonemum closed, the fascia of the rectus sheath is overlapped and sutured in position. The transverse incision is usually employed.

AFTER-TREATMENT

In cases of strangulated hernia the usual post-operative treatment to combat toxæmia and shock is carried out, and stomach lavage is continued until the patient ceases to vomit.

PREVENTION OF STRANGULATED HERNIA

I have already stated that over 2,000 people die yearly from strangulated hernia, and I hope I have outlined a method by which this mortality can be reduced; but if things continue as they are we shall still have a heavy death roll. There is a way, and only one, by which we can eradicate this mortality; that is a radical cure of the hernia as soon as it appears. Wilkie² has stated:

"If we are to reduce the distressingly high mortality in acute intestinal obstruction I believe we must spread the knowledge of the early signs of the malady, first, among our students and practitioners, and secondly, among the public, through our health organizations."

There can be no doubt as to the wisdom of these words in cases other than strangulated hernia, but why in this condition should we advise students and practitioners to await until strangulation has occurred? We have taught them in the past the wisdom of removing a troublesome appendix before it can cause serious symptoms; surely the time has come to teach them the same about a hernia. As to the public, we can teach a certain class, but there is a far larger class which we shall never educate. I have heard this "spreading of knowledge" advocated ever since I qualified, but one has only to refer to the Registrar-General's returns (Table III) for the decade 1921-30 to realize that this is bearing little fruit, for strangulated hernia is on the increase.

TABLE III.—Registrar-General's Returns, 1921-30

Cause of Death	Sex	1921	1922	1923	1924	1925	1926	1927	1928	1929	1930
Strangulated hernia	M	752	830	822	867	830	842	957	593	1,090	950
	F	930	885	916	947	931	923	1,008	974	1,029	1,032
Appendicitis	M	1,474	1,524	1,608	1,545	1,621	1,535	1,524	1,623	1,657	1,693
	F	1,237	1,211	1,218	1,211	1,238	1,175	1,236	1,245	1,159	1,248

If one refers again to Table III and compares the death rate for strangulated hernia during the past decade with that of appendicitis one must be struck with the nearness of approach of these figures. No medical man would allow a patient to go about with a grumbling appendix, yet the country is teeming with men and women going about their daily work with hernias, not realizing that the mortality nearly approaches that of appendicitis. Are medical men fully alive to the significance of these figures, and, more important, do they impress the meaning of them on their patients? I think the answer must be in the negative, for I know of no greater prejudice among general practitioners than that against advising operative cure for hernias in patients over the age of 45.

It is not my wish in this paper to disparage general practitioners in any way, but I cannot help feeling that the safety of this operation at the present time is not wholly realized by them. I hope that any who read this paper will acknowledge that I am making full allowances for their views when I say that up to a few years ago theirs was the accepted teaching—namely, that it

was unwise to operate on such cases, as there was invariably recurrence. But since then Gallie has come forward and shown us how recurrence can be prevented by the use of fascial grafts. Gallie's operation consists in taking strips of fascia lata from the thigh and interlacing them across the hernial opening. I have performed this operation on several occasions with most satisfactory results, but I only employ it in very large hernias where the tissues have been greatly stretched. The operation of fascial repair which I have previously described is a modification, and has the advantage of being a living graft. This operation performed under local anaesthesia is perfectly safe, and recurrences do not take place.

The technique of the operation is the same as I have described above. In elderly patients I give an injection of ephedrine about ten minutes before the operation is started; this greatly lessens any tendency to shock. Should they have a double hernia I perform two operations at fortnightly intervals. On returning to bed the patient is placed in the sitting position, and provided everything is satisfactory he is allowed to sit out of bed on the second or third day. This procedure is to be highly commended, since it lessens the chances of pulmonary complications, and provided there is no strain on the fascial graft, it can do no harm.

The truss has still its adherents, and will continue, I suppose, for the present, to have a certain amount of popularity. If it fulfilled all that is claimed for it, strangulated hernia would be unknown. When we remember that some 11,000 people are operated upon yearly we cannot with a clear conscience consider it as a satisfactory form of treatment. For some years I have invariably advised a radical cure for all types of hernia, and so far I have had no reason to regret this advice. All patients over 40 are operated upon under local anaesthesia. Table IV shows the number of patients, with age

TABLE IV.—Operations upon Non-strangulated Hernia under Local Anaesthesia

Age	No. of Cases	Deaths
31-40	4	—
41-50	16	—
51-60	18	—
61-70	27	—
71-80	9	—

incidence, on whom I have performed this operation, and I have not yet lost a single case. The few under 40 were operated upon because of complications, usually pulmonary.

In conclusion I should again like to stress the safety of this operation and the enormous saving of human life resulting from its timely use.

At a recent meeting of the Permanent Committee of the International Office of Public Health, Sir George Buchanan gave an account of an outbreak of acute poliomyelitis which had occurred six weeks after the commencement of the summer term in a boarding school in the country, containing eighty-eight boys aged from 10 to 18. Between June 10th and 30th, 1933, eleven boys contracted the disease, of whom five recovered completely in two to six days, two in a somewhat longer period. The four developed paralysis, and one died in four days. The chief points of interest in the outbreak were its intensity and short duration, the small number of cases in which paralysis actually occurred, and the rapidity of recovery, in spite of the severity of the symptoms in several cases. No convalescent serum was used in any case.

VITAMINS A AND D: THEIR RELATION TO GROWTH AND RESISTANCE TO DISEASE

BY

ROBERT SUTHERLAND, M.D., D.P.H.

ASSISTANT MEDICAL OFFICER OF HEALTH, ABERDEENSHIRE

Within the last twenty years, and especially during the last decade, there has accumulated an extensive literature on the subject of vitamins, which shows clearly that an adequate, though minute, amount of these accessory food factors in the diet is essential to the proper functioning of the animal organism. Of the vitamins so far known, two of the most important are the fat-soluble vitamins A and D.

VITAMIN A

Our knowledge regarding the functions of vitamin A has been gained largely as the result of animal experiment. It has been found that a deficiency of this vitamin interferes with the rate of growth in animals^{1, 2, 3}; produces a metaplasia and keratinization of mucous epithelia cells^{4, 5, 6, 7, 8, 9}; and increases the susceptibility to local infections of the degenerated epithelia.^{4, 8, 9, 10, 11, 12, 13} No evidence of any effect upon general resistance to disease has been forthcoming.

It would be unwise to assume, however, that conclusions drawn from animal experimentation can be rigidly applied to human beings in whom deprivation of vitamins is conditioned by naturally arising dietary deficiencies. For humane reasons the complete withdrawal of all vitamin A from the diet is impossible. When compared with animal experiments, therefore, where it is the rule that the basal diet is complete and well balanced except for the absence of the vitamin to be tested, human experiments are complicated by the fact that the basal diet of many of the subjects is incomplete and imbalanced, and that the vitamins which are being investigated are only partially, if at all, deficient. Consequently it has been difficult to obtain clear-cut results in man.

Hess found no evidence of vitamin A supplements improving the rate of growth of children¹⁴; and only one case has been reported where the degenerative changes of epithelia occurred as in animals.^{7, 15} Further, the evidence concerning the effects of vitamin supplements upon susceptibility to infection and resistance to established disease is conflicting, since a relation between vitamin A deficiency and infections has been found by some investigators,^{16, 17, 18, 19, 20, 21, 22, 23} while it has not been observed by others.^{14, 24, 25, 26, 27}

VITAMIN D

It is now generally recognized that a deficiency of vitamin D interferes with the metabolism of calcium and phosphorus.^{28, 29, 30, 31, 32, 33, 34, 35} When this fact is coupled with the observation that a slowing of the rate of growth of animals follows an upset of the calcium or phosphorus content of the blood,^{28, 37, 38} it seems highly probable that an optimum amount of vitamin D is necessary if maximum growth is to proceed. Experiments on vitamin deficiency support this view.^{32, 35} Whether or not vitamin D plays any part in determining susceptibility to infection is as yet unproved, as the evidence of different observers is at variance.^{9, 13, 36, 39}

AN EXPERIMENT UPON SCHOOL CHILDREN

In view of the uncertain state of our knowledge concerning the prophylactic and curative value of vitamin supplements in man, and having regard to the fact that large amounts of these substances are being prescribed

at considerable expense to the general community, it was felt that there was a definite need for a test of such preparations by a controlled experiment. Accordingly, for a period of six months during the winter and spring of the school session 1931-2, a concentrate of vitamins A and D was administered to 294 children of both sexes and of all ages from 5 to 15, attending the North School, Peterhead. These children were selected at random, and bad as controls 281 contemporaries. It was shown by a census of the parents' occupations that the pupils of this school were drawn almost entirely from the lower working classes.

The purpose of the experiment was to study the effect of the addition of supplements of vitamins A and D to the average home diet of children of the poorer classes. The effects that were especially looked for were those upon growth, general nutrition, susceptibility to infection, and resistance to established disease.

For a period of six months from November 9th, 1931, to May 15th, 1932, each child in the treated group received one capsule of the vitamin concentrate twice daily—one in the morning and one in the afternoon of every day upon which it attended school. Each child in the control group was given instead, but at the same time, an arabis oil capsule, which was similar in taste but entirely deficient in vitamins. According to the statement of the manufacturers, one capsule of the vitamin concentrate contains 1,000 blue units (Carr-Price value) of vitamin A, and 1,200 international units of vitamin D. The children in the treated group were thus receiving the equivalent in vitamin A of over one ounce of cod-liver oil during each day that they attended school.

Children who consistently experienced difficulty or showed marked distaste when swallowing the capsules were eliminated during the first three weeks, and, before the experiment was concluded, others were eliminated because they were suffering from tuberculosis or other serious illness, or because they had left school, or because they were absent at the time of the second examination. In the last event, however, they were included in the observations recorded below regarding the incidence of disease. By all these eliminations the numbers in the experiment were reduced from 326 in the experimental group and 325 in the control group to 294 and 281 respectively.

MEASUREMENTS

Each child was physically examined at the beginning and at the end of the experiment by the writer, who did not know to which group the pupil belonged. It was found impracticable to weigh the children without clothing, and they were therefore weighed and measured in their indoor garments. In order that a fair comparison might be made between the findings at the two examinations, however, the number of garments was counted on each occasion, an average weight per garment was determined for each 2-year age group, and an allowance was made for any difference in the number of garments at the second examination. The height was measured without footwear to the nearest eighth of an inch, and the weight to the nearest eighth of a pound.

CLINICAL OBSERVATIONS

It was recognized, of course, that quantitative measurements are the most reliable of the observations that can be made at a physical examination, but a wealth of other valuable criteria of comparison of health and of resistance to disease would have been lost had the examination been restricted to them.

If the examiner is unaware which of his subjects belong to the experimental group and which to the control group, if he sets down in writing fixed standards by which

he can measure the degree of abnormality of each factor and to which he can refer before undertaking the second examination, if each individual is examined for the presence or absence of all the factors which are to be analysed, and, most important of all, if examinations from which comparisons are to be made are carried out by the same observer, then these "clinical" observations may be of the utmost value as data of comparison. In the present instance all these requirements were met, and the data in question were obtained by the use of certain standards which, though they might vary with each examiner, were reasonably constant when used by the same observer at both examinations. Observations based on these fixed standards were made upon the general nutrition and development of the child; its posture; the width of the subcostal angle and the breadth of the shoulders; the development of the breasts in females; the condition of the teeth; the presence or absence of enlargement of the tonsils and of the cervical lymphatic glands, of nasal catarrh, of external eye disease, of nail biting, or of anaemia, as determined by a clinical examination of the conjunctiva, lips, palate, and finger-nails; and the degree of cleanliness as measured by the presence or absence of head-nits or vermin and of flea-bites on the body. It will be noted that observations were made on certain factors upon which the vitamin concentrate could not be expected to have any effect. Such observations, however, were found to be of value in establishing the initial comparability of the groups.

RECORD OF ILLNESS

In order that an indication might be obtained of the effect, if any, of the vitamin supplements upon susceptibility to infection and resistance to established disease, a record of the number of days of illness from specified diseases observed in school or the cause of absence was kept by the teachers from January 5th to May 20th, 1932, in the case of every child. This record was kept on a form upon which a dated space was left for each school day, and illnesses were noted under appropriate headings.

The records of illness causing absence were compiled from medical certificates, or from information supplied by the attendance officer. Illnesses observed in school were the record of the class teacher's observations. The writer, however, visited the various classes on an average once a week, checked the observations of the teachers, demonstrated new conditions, and generally exercised reasonable supervision. In this way the degree of accuracy of the observations made was kept at a high level. The numbers observed as regards the incidence of sickness were 294 in the treated group and 288 in the control. These numbers differ slightly from those examined physically because some were absent at the time of the second examination.

INITIAL EQUALITY OF THE GROUPS

Space does not allow a detailed account of the methods by which the initial equality of the groups was proved. Suffice it to say that a careful comparison of the original heights and weights and of the data obtained from all the observations referred to under the heading "clinical observations" served clearly to establish the comparability of the groups at the beginning of the experiment.

COMPARISON OF THE FINDINGS OF THE TWO EXAMINATIONS

With the similarity of the groups at the beginning of the experiment satisfactorily determined, it is possible to proceed to a consideration of such of the data as will indicate if any significant difference between the two

groups existed at the close. A comparison of the gains in height and weight in the two groups during the period of the experiment will determine if there was any difference in the rate of growth, but, in order to make the comparison a fair one, the gains must be expressed as a percentage of the original measurements. This is done in Table I, from which it will be seen that the treated groups show a slight advantage in respect of the gains in both height and weight. If both sexes are taken together, the treated group shows an average gain in height and in weight of 2.3 and 5.3 per cent. respectively of their original measurements, compared with 2.1 and 4.9 per cent. respectively in the controls.

TABLE I.—Average Gains in Height and Weight at all Ages in the Respective Groups

Observations	Groups					
	Females		Males		Both Sexes	
	C	T	C	T	C	T
Number of children in groups at all ages	146	149	135	145	281	294
Height:						
Average at first examination (inches)	50.288	50.087	49.104	48.724	49.719	49.411
Average at second examination (inches)	51.360	51.235	50.101	49.818	50.775	50.534
Actual average gain in inches at second examination	1.072	1.148	0.997	1.094	1.075	1.121
Average gain expressed as percentage of average height at first examination	2.1	2.3	2.0	2.3	2.1	2.3
Weight:						
Average at first examination (pounds)	59.699	59.705	57.844	56.818	58.823	58.256
Average at second examination (pounds)	62.833	63.128	60.455	59.190	61.691	61.383
Actual average gain in pounds at second examination	3.134	3.423	2.611	2.742	2.883	3.087
Average gain expressed as percentage of average weight at first examination	5.2	5.7	4.5	4.8	4.9	5.3

C = Control. T = Treated.

The extent to which the gains in height and weight in the treated groups exceed those of the control group can also be expressed as a percentage of the control gains. This method shows that the treated group as a whole gained 8 per cent. more in height and 7 per cent. more in weight than did the control group.

An examination of any changes in the state of nutrition in the two groups is another observation which may fairly be regarded as an index of the rate of growth. This was done in two ways: first by comparing the numbers in the various nutritional categories (better than normal, normal, subnormal) in the groups as a whole at the first and second examinations; and secondly, by noting at the end of the experiment whether the nutrition of each individual had improved, deteriorated, or remained unchanged. By this means it was found that there was, in the case of both these observations, a slight balance in favour of the treated group. This accords with the findings regarding height and weight.

In summing up the results of a statistical analysis of the data, which he was kind enough to make, Dr. J. O. Irwin of the London School of Hygiene and Tropical Medicine reported that the balance in favour of the treated group was significant for height in males but not in females, and not significant for weight in either sex. In view of this report the value of the supplements in the promotion of growth must be regarded as, at best, slight.

In order to determine if any effect upon the resistance to local infection had been obtained the relative frequency of abnormal conditions of the tonsils, lymphatic glands, nose, eyes, and skin was studied in the various groups

TABLE II.—Summary of the Results of the Different Observations upon the Susceptibility and Resistance of the Various Groups to Colds

School or Absence	Observations	Females			Males			Both Sexes		
		C	T	T Excess	C	T	T Excess	C	T	T Excess
School	1. Average amount of illness in days	5.037	5.671	+0.634	7.212	5.970	-1.242	6.014	5.837	-0.207
	2. Percentage affected	36	43	+7	48	43	-5	42	43	+1
	3. Average number of separate illnesses	0.756	0.913	+0.157	1.236	1.022	-0.214	0.959	0.953	-0.006
	4. Average duration in days of each illness	6.7	6.2	-0.5	5.8	5.8	0	6.2	6.0	-0.2
Absence	1. Average amount of illness in days	1.263	1.3.6	+0.053	1.095	1.0.7	-0.052	1.183	1.150	+0.002
	2. Percentage affected	19	17	-2	17	20	+3	18	18	0
	3. Average number of separate illnesses	0.233	0.205	-0.028	0.197	0.216	+0.019	0.233	0.210	-0.023
	4. Average duration in days of each illness	4.8	6.4	+1.6	5.6	4.8	-0.3	5.1	5.7	+0.6

C = Control. T = Treated. School = Cold observed in school. Absence = Cold causing absence.
 - = Balance in favour of the vitamin supplement. + = Balance against the vitamin supplement.

at the close of the experiment. Here again, as in the case of nutrition, two methods of comparison were adopted. In the first place, the condition of the groups as a whole at the end of the experiment was compared with regard to the presence in any degree of the factor under review; and, in the second place, a comparison was made of the individual improvements and deteriorations. As a result no definite evidence was found of the vitamin supplements having been of use in the prophylaxis or treatment of any of the conditions studied by this means.

COMPARISON OF THE RECORDS OF ILLNESS

In order to determine from the records of illness if there is any evidence of difference in the resistance to disease of the two groups several methods may be adopted. A broad indication of any differences in the general resistance of the groups will be obtained from a comparison of the average number of days of illness from all, and from specified causes; the presence or absence of a diminished susceptibility to infection in the treated group will be indicated by a comparison of the percentage of cases in which illness from the various causes occurred, and by a comparison of the average number of *separate* illnesses in the groups; and, lastly, any effect upon the resistance to established disease will appear from a comparison of the average duration of each *separate* illness. All these methods appear to be of value, and were accordingly used in the case of all the diseases observed in school or causing absence.

When the average number of days of illness from all causes, except pulmonary tuberculosis, was compared in the groups no evidence of an increased resistance to disease was found in the treated group. Actually the treated boys and girls averaged one and a half more days of illness in school than the controls. As far as absence from school is concerned, however, the groups were equal, with an average of approximately four and a half days' illness.

In the same way, when the data regarding the incidence of the specified diseases, colds, sore throat, influenza, infectious diseases, skin disease, eye disease, and ear disease were examined in detail by the various methods described above, no definite evidence was forthcoming of diminished susceptibility to infection or increased resistance to established disease. Accordingly it is not proposed to include the tables showing the results of these methods of analysis.

It has been thought worth while, however, to marshal the evidence concerning colds in Table II. This has been done, first, because of the claims that are made for

vitamin A supplements as a prophylactic against colds, and, secondly, on the assumption—reasonable in the light of the experimental evidence—that if these supplements have any prophylactic or therapeutic value they will show it in the case of mild infections of mucous epithelia. Incidentally this procedure will serve to show how all the data were analysed. From Table II, then, it will be seen that no significant differences have been found in the groups as a result of any of the observations made. The vitamin supplements therefore had no prophylactic or therapeutic effect upon the common cold.

QUESTIONNAIRE TO PARENTS

At the conclusion of the experiment a questionnaire was sent to the parents of all children in the control and treated groups. They were asked to state their opinion of the effect of the capsules upon the health and the appetite of their children. In order to encourage them to give an unfavourable verdict if they thought it merited, they were informed that two forms of the preparation had been used and that their help was required to determine which was the better.

In approximately 80 per cent. of each group an improvement of both health and appetite was reported—surely a striking example of the power of suggestion upon the human mind, and a warning of the necessity of judging the value of such preparations by controlled experiments rather than by "impressions."

DIETARY SURVEY

The writer is indebted to Dr. J. B. Orr and Mr. W. Godden of the Rowett Research Institute for information concerning a survey of the diets of sixty-six Peterhead families, which they carried out during the course of the experiment.⁴⁰ The diet of these families may fairly be considered to be representative of that of the children attending the North School, Peterhead, as in each case at least one member of the family was a pupil of that school. From this information Table III has been compiled. In it the findings of the 1932 survey are compared with those of 1927 in largely the same families, and with the British Medical Association standards⁴¹ for calories, protein, carbohydrate, and fat, and McLester's standards⁴² for minerals. In addition, the percentages of the sixty-six families below the average and below the standards are shown.

It will be seen that there is a notable lowering of the amounts of all the constituents of the diet in 1932 as compared with 1927, when Orr and Clark⁴³ stated that it was more than probable there was a deficiency of some

of the vitamins, especially vitamins A and D. Further, in the case of all the constituents, more than half of the families are below the average, and the great majority are below the standards. Commenting upon the high calorie intake in 1927, the authors¹³ considered that there was either an unnecessarily high consumption or excessive waste. This is explained, no doubt, by the fact that the herring fishing was very successful in 1926 and 1927. As Peterhead is chiefly a fishing town everyone shared in this prosperity; 1930 and 1931, on the other hand, were poor fishing years, and it is not surprising, therefore, to find the dietary giving evidence of decreased purchasing power, as indicated in Table III.

TABLE III.—Results of a Dietary Survey of Sixty-six Peterhead Families in 1932 compared with that made in 1927 and with Certain Standards.

Constituent of Food	Average Amount Purchased per Man Unit per Day (Grams)			1932 Survey	
	1927 Survey	1932 Survey	B.M.A. and McLester's Standards	Percentage of Families Below the Average	Percentage of the Families Below the B.M.A. and McLester's Standards
Protein...	125.1	80.5	100.0	56	82
Carbohydrate	685.7	431.9	500.0	56	80

Phosphorus ...	2.14	1.27	1.50	63	80
Iron ...	0.021	0.0115	0.015	55	83
Calories ...	4,120	2,629	3,400	53	85
Income in shillings	1.52	1.18	—	56	—

A study of the actual foodstuffs purchased affords valuable information concerning the vitamin content of the diet. The average amount of milk bought per man value per day was one-third of a pint. There was a marked lack of animal fats—only one-third of a pound out of every 100 lb. of food purchased being butter—and the consumption of animal foods was low. Vegetables and fruit were used very sparingly indeed. It seems probable, therefore, that, although no evidence of vitamin deficiency so gross as to produce xerophthalmia was found, the vitamin content of the diet did not amount to the optimum requirements. The observation that the addition of vitamins A and D to the diet produced a slight improvement in the rate of growth supports this conclusion.

AVERAGE DAILY ATTENDANCE

The average daily attendance, expressed as a percentage of the average daily roll, is the best index of the amount of illness occurring in a school. This figure for the period of the experiment has been compared with the average for the same months during the preceding five years. The figures are: 86.6 per cent. for 1931–2, and 86.4 per cent. for the preceding five years. The period of the experiment may be regarded, therefore, as occurring during an average year.

DISCUSSION

The results of the administration of vitamin supplements to children whose diet was considered to be deficient in them are disappointing. Not only has no conclusive evidence of any beneficial effect upon susceptibility to infection or resistance to established disease been demonstrated, but the effect upon growth compares unfavourably with that observed in the milk experiments of Orr¹⁴ and Leighton and Clark¹⁵ in 1927 and 1928, as shown in Table IV. The North School, Peterhead, was one of the schools chosen for these experiments, and the interval

between the first and final measurements was the same seven months of the year.

It will be seen, then, that the basal diet + vitamins A and D and other constituents of milk produced a material improvement in the rate of growth, whereas the basal diet + vitamins A and D *without* the other constituents of milk produced only a slight improvement. Therefore the supplement of vitamins A and D failed to produce substantial improvement because of a deficiency in the basal diet of some or of all of the other constituents of milk. Of these deficiencies perhaps the most important were those of first-class animal protein and of minerals. The protein content of the diet was drawn in

TABLE IV.—Comparison of the Increases of Height and Weight in the Various Groups in the 1927 and 1928 Milk Experiments¹⁴ and in the Peterhead Vitamin Experiment.

Experiment	Group	Number in Group	Height Increase (All Ages) (Inches)	Weight Increase (All Ages) (Pounds)
1927 Milk experiment	Milk Non-milk	551 731	1.470 1.232 = + 0.258 (i.e. 21.29%)	3.617 2.974 = + 0.643 (i.e. 21.62%)
1928 Milk experiment	Milk Non-milk	567 590	1.453 1.1810 = + 0.2775 (i.e. 23.50%)	3.576 2.4510 = + 1.116 (i.e. 45.37%)
1932 Vitamin experiment	Treated Controls	234 241	1.122 1.035 = + 0.085 (i.e. 8%)	3.087 2.883 = + 0.204 (i.e. 7%)

+ = Balance in favour of the treatment.

large measure from starchy foods, and consequently was of poor biologic value. As for the mineral content of the diet, although the averages both for calcium and for phosphorus were only just below Sherman's standards¹⁶ of 0.68 and 1.32 grams respectively in the 1932 survey, the fallacy must be avoided of regarding a satisfactory average established by a dietary survey as an indication that all members of the group investigated are receiving adequate amounts of the substance under review. Actually, in the case of calcium and phosphorus, 55 and 62 per cent. respectively of the families were below the average. The average figure, therefore, tends to create a false impression of the true state of affairs. It was by supplying deficiencies in those below the average and bringing their rate of growth up to that of their more fortunate fellows that the milk supplements effected the raising of the average rate of growth.

It appears clear, then, that the milk supplements succeeded where the vitamin addenda largely failed, because, in addition to correcting the vitamin deficiency, they made good the associated deficiencies which almost always go hand in hand with a shortage of vitamins. The correction of one partial deficiency in man, while other associated deficiencies remain uncorrected, can never produce the dramatic results that are obtained from the restoration to the otherwise complete diet of experimental animals of a factor which was previously entirely absent. That this applies to the question of susceptibility to disease as well as to growth is shown by McCarrison's work in India.¹⁷ He found that rats fed on a completely balanced diet were practically free from disease, while animals living in the same environment, but on badly balanced diets, suffered the whole gamut of human ailments. He stated, further, that the most disease-producing of these diets was one of "white bread, margarine, tea, sugar, jam, preserved meat, and scanty, overcooked vegetables." The Peterhead dietary survey showed that

such a diet was extremely common. The correction of only one of its many errors could not then be expected to compensate for all its other deficiencies.

As the optimum requirements in man are not known it has been possible to produce only presumptive evidence that the dietary of the treated children was deficient in vitamins A and D. The diet, as a whole, however, was so bad that few people in this country can be faring worse. If these children were not suffering from a vitamin deficiency, therefore, the condition must be relatively uncommon. Whether the vitamin supplements failed to produce striking results for the reasons suggested—namely, the failure to correct associated deficiencies, or because no vitamin deficiency was present—the fact remains that little benefit resulted from the administration of vitamin concentrates to those members of the community who had been shown by an investigation of their diet to be among those most likely to receive benefit.

On biological grounds, then, there can be no comparison between the value of milk and that of vitamin concentrates as supplements to a defective basal diet. To this there is added the potent economic argument that not only does milk produce better results than vitamin concentrates, but it does so at no greater cost. The time has come when the public must be educated to realize that vitamin supplements do not constitute a nutritional short cut to health. A vitamin concentrate can correct only a vitamin deficiency; it has no magic power of assuming the functions and properties of other essential factors of the diet. The metabolism of food in the body is a chemical process, and if this process is to proceed to the best advantage the correct constituents must be present in sufficient quantity, and they must be present in approximately correct proportions.

SUMMARY

1. A dietary survey in Peterhead showed that the diet of many families of the poorest classes was grossly inadequate in several respects, and presumably deficient in vitamins A and D.

2. A concentrate of vitamins A and D was therefore administered for six months in daily doses equivalent in vitamin A to rather more than one ounce of high-grade cod-liver oil to 294 school children of the lower working classes in Peterhead; 281 contemporaries acted as controls.

3. The rate of growth of the treated children appeared to be only slightly better than that of the controls.

4. Susceptibility to infection and resistance to established disease were apparently unaffected by the treatment.

5. Evidence is produced to suggest that the cause of this failure lay in the fact that the vitamin supplements made good only one dietary deficiency and left uncorrected associated deficiencies of equally essential constituents of the diet.

6. The importance of a well-balanced dietary is therefore stressed, and the value of milk supplements, as a step in this direction, is compared favourably on both biological and economic grounds with that of vitamin addenda.

This experiment was made possible by the generosity of the manufacturers of the vitamin concentrate, who placed large quantities of their product at the disposal of Professor L. S. P. Davidson of Aberdeen University, by whom, in turn, the concentrate was made available for the Peterhead experiment. To him I am deeply indebted, also, for his never-failing interest and advice. In addition, I wish to thank Dr. Harry J. Rae, chief regional medical officer of health, Aberdeen, Aberdeenshire, and Kincardine, for his kindness in affording me every facility in carrying out the work, and Dr. J. B. Orr and Mr. W. Godden of the Rowett Research Institute, Bucksburn, for supplying me with valuable information and much helpful advice. I am especially grateful to Mr. W. G. Mair, head master of the North School, Peterhead, and his staff for their constant courtesy and helpfulness, without which the experiment could not have been carried out.

The returns from universities and university colleges in receipt of Treasury grants for the academic year 1932-3 have now been issued by the University Grants Committee (H.M. Stationery Office, 1s. 3d.). Of the 50,155 full-time students to which this publication relates, medicine and dentistry claim 11,247; of these 9,835 were men and 1,412 women. Edinburgh and Glasgow Universities head the list with totals of 1,233 and 1,067 respectively. The schedule of degrees and diplomas obtained during the year and analysed according to faculties gives a total of 1,055 degrees and 1,183 diplomas under "medicine including dentistry" in Great Britain.

RECENT ADVANCES IN ANAESTHETICS *

BY

RONALD JARMAN, M.R.C.S., L.R.C.P.

ANAESTHETIST TO THE CANCER HOSPITAL; SENIOR ANAESTHETIST,
PRINCESS BEATRICE HOSPITAL, AND WOOLWICH MEMORIAL
HOSPITAL

There are three main types of anaesthesia in use to-day: (1) inhalation combined with premedication, (2) spinal combined with premedication, and (3) intravenous, with or without premedication. I will deal with them in this order.

Before considering the anaesthetics themselves it is advisable to stress an important point—namely, that all patients who are to undergo a major surgical operation ought to be carefully investigated. This should include a blood and urine analysis, in addition to a general clinical examination. Special attention is paid to the blood pressure and the Moot-McKesson cardiac energy index. The formula for this index provides an approximate index to the cardiac reserve.

$$\text{Moot's index} = \frac{\text{pulse pressure} \times 100}{\text{diastolic pressure}} = 50 \text{ (in normal subjects)}$$

Patients presenting an index of between 40 and 60 show ample cardiac reserve; those in whom the index lies between 25 and 40, or between 60 and 75, have probably adequate cardiac reserve, whilst the reserve is gravely inadequate in those having an index below 25 or above 75. (This index is unreliable in cases of thyrotoxicosis, owing to the high pulse pressure.) No enemata, purges, or any other form of dehydration should be permitted for at least forty-eight hours before any major operation. The patient is supplied with ample fluids and glucose, and everything is done to ensure that his general condition is the best the pathological state allows.

Inhalation Anaesthesia with Premedication

The public has lately become aware of the tremendous advantages which are derived from being put to sleep in their own beds, and many patients more or less demand some drug that will bring about complete oblivion before any type of operation. For this purpose the chief drugs that we have at our disposal are as follows. First, the popular barbiturate group, which includes nembutal, sodium amytal, pernocton, medinal, di-dial, and the latest—evipan. All these may be given intravenously except medinal, and all may be administered orally except pernocton. Evipan appears to be the least toxic of all the barbiturates. The next group consists of drugs administered per rectum, such as avertin, paraldehyde, and ether-olive-oil emulsion.

It is possible to produce a mild surgical anaesthesia with any of these drugs, and they may be used either as premedication to inhalation anaesthesia or as the total anaesthetic. For the latter purpose, however, large doses must be given, and toxic effects are apparent. Headaches, nausea, and vomiting have been reported following the use of all these drugs—complications which have rarely been seen when evipan has been the sole general anaesthetic. With evipan, induction and return to consciousness are much more rapid than with any other barbiturate, and if reasonable care is used it does not appear possible to give a fatal dose. Patients generally prefer an intravenous injection to either a rectal or inhalation anaesthetic. A combination which has proved efficacious over a very large number of cases is that of omnopon and scopolamine, the dose varying according to

age. The routine dose is omnopon 2/3 grain, scopolamine 1/150 grain, and these amounts may be given to patients between the ages of 16 and 65. It is fairly easy to produce the desired effect with any of the drugs mentioned above, and each has its merits.

In my opinion the best type of inhalation anaesthetic to use after them is nitrous oxide and oxygen. This is best given at varied pressures with an apparatus such as the McKesson.

Before and during the war the most popular anaesthetics were chloroform and ether. Why, one asks, have they fallen into disuse with up-to-date anaesthetists? It is on account of the complications which frequently follow their administration to dangerously ill patients. The complications following chloroform and ether are many and well known. They are: delayed chloroform poisoning, sudden collapse or status lymphaticus, chest complications, bronchitis, bronchial pneumonia, lobar pneumonia, pulmonary collapse, paralytic ileus, post-operative vomiting, and shock. It became essential to find another anaesthetic which would reduce these complications, particularly the shock. Nitrous oxide and oxygen, combined with only small amounts of ether, was the result.

ADVANTAGES OF N₂O-OXYGEN AS AN INHALANT

The use of nitrous oxide and oxygen considerably lessens the incidence of the complications described above. Its particular advantages are as follows.

1. It is the safest and the least toxic of all general anaesthetics, and there is therefore little sensitization of the tissues to surgical shock. It is pleasant for the patient at the time of induction, even if little or no premedication has been given, while sufficiently large doses of narcotics may with safety be given beforehand, so that after the operation the patient cannot remember that he was removed from his bed.
2. Surgical relaxation is quickly obtained when required.
3. Operations with the diathermy knife can be done with absolute safety.
4. Bodily functions are scarcely interfered with, and the clinical state is not aggravated.
5. The most desperate cases may be operated upon with comparative safety so far as the anaesthetic is concerned.
6. Dangerous signs of an overdose are conspicuous enough to give timely warning, and the respiratory centre remains responsive until late.
7. In the absence of premedication, recovery of consciousness and rational control is almost immediate, even after prolonged administration.
8. The after-effects are conspicuous by their absence. There is never any vomiting, except when it is caused by other conditions, and so thirst may be quenched and nourishment taken soon after the operation.
9. The anaesthetic may with safety be repeated many times at short or long intervals.
10. The stay in hospital is shortened and the convalescent period is reduced.

The advantages of the McKesson apparatus are as follows.

1. It delivers the mixture at the percentage desired, whether the breathing is shallow or deep, whether re-breathing is employed or not, and whether the pressure of the gases is high or low.
2. The percentage of oxygen can be varied accurately, definitely, and simply.
3. Rebreathing can be employed at all pressures.
4. The pressure at which the gases are delivered can easily be varied at will without disturbing the percentage of oxygen in the mixture.

* Read before the Chelsea Clinical Society and the Watford Division of the British Medical Association.

The scope of nitrous-oxide-oxygen anaesthesia is unlimited. By means of the ordinary facepiece any operation may be performed, though spinal analgesia gives a better relaxation for abdominal work. In order to exteriorize the larynx a transnasal intratracheal tube may be passed, which prevents anything from going down into the trachea or a bronchus. A direct intratracheal tube may be passed for nasal operations, and the field of operation can be completely closed off and the patient entirely covered without any danger whatsoever. Dental operations and tonsillectomy can also be done with safety. Further, this form of anaesthesia is extremely valuable in all cases of midwifery, whether it be a natural delivery, a forceps case, or a Caesarean section. It can be given intermittently during the first two stages, and continuously for the third. The uterine contractions are actually strengthened, thus shortening the time of labour. The mother's condition is definitely better than when chloroform is used, and the baby is not affected in any way, and usually cries as soon as it is born.

OTHER INHALANTS

Apart from nitrous oxide, there are two other gases that are in use to-day. One, ethylene, has been employed for some years; the other, a new gas called cyclopropane, is in the process of being investigated.

Ethylene has had many advocates, but owing to its unpleasant odour and the possibility of an explosion it has not come into general use. The great advantage of this gas is that it gives a deeper and quieter anaesthesia than nitrous oxide and oxygen alone, and enables a higher percentage of oxygen to be given.

Cyclopropane (trimethylene) is a hydrocarbon gas, an isomer of ethylene. It produces an anaesthesia as deep as that from ether, and the induction and return to consciousness are as quick as is the case with nitrous oxide. It is extremely potent, and oxygen from 75 to 90 per cent. has to be given with it. As yet only one cylinder of this gas has to my knowledge been used in this country, and it is difficult, therefore, to give an opinion on it; but so far as one can see it has real possibilities. A full report has been made by its users at the University of Wisconsin Medical School, U.S.A.

Spinal Analgesia with Premedication

With spinal analgesia I usually employ omnopon and scopolamine premedication, and sometimes supplement this with evipan. The advantages of a spinal anaesthetic are as follows: (1) it can be employed in certain cases where an inhalation anaesthetic must be avoided; (2) it produces a complete anoci-association—that is, cutting off of all apparent pain impulses—and it provides an adequate relaxation in abdominal surgery; (3) as spinal analgesia does not increase the sensitization of the tissues with histamine, the resulting shock to the patient is considerably less than with an inhalation anaesthetic such as ether or chloroform.

There are, however, certain disadvantages as well—namely, headaches, which occur in 1 per cent. of cases; pain in the back (0.02 per cent.); severe nausea and vomiting (0.5 per cent.); paralysis (0.01 per cent.); and sudden collapse (0.01 per cent.). There is also a definite fall in blood pressure, and this varies with different types of patient.

THE SOLUTION

The solution I prefer for a spinal analgesic is percaine, though I have also used stovaine, spinocain, etc. Percaine is the least toxic of the preparations. Its effect

upon the blood pressure is considerably less than that of any other spinal analgesic, while, as it has a prolonged and lasting effect covering from one to three hours, the surgeon need not work against time. A high abdominal anaesthesia can be produced with a maximum of safety, and the same solution may be used to infiltrate the skin before introducing the intrathecal needle. The anaesthesia is so enduring that the patient is free from pain for from six to twelve hours after the operation, and the amount of narcotics required is thus minimized. This is particularly valuable with piles and operations on the perineum, and others that give a great deal of discomfort. Finally, a smaller number of headaches occur than is the case when stovaine, etc., are used.

Percaine is used in two strengths—the dilute (20 c.cm. of a 1 in 1,500 solution) and the strong (2.3 c.cm. of a 1 in 200 solution). The dilute solution is being used more often than the other, and this is the one I employ myself for all types of operation, though the stronger is most useful for operations of the perineum, etc., where small doses from 0.6 c.cm. upwards to the full dose may be given.

Operations such as removal of piles, cystoscopy, and prostatectomy may be done with this strong solution with ease. It may be given either in the lateral or the upright position, and the operation can be proceeded with almost at once. Certain operators mix this solution with the spinal fluid, but this course is not necessary unless one requires anaesthesia at a slightly higher level than that of the crest of the ilium.

TECHNIQUE OF ADMINISTRATION

There are two quite different methods of administering the dilute solution. The one most frequently used is known as the Howard Jones technique; the second, which has only recently been brought to notice, is the Etherington Wilson technique. I have used the former for my last 1,200 cases, and it is performed as follows:

One hour before the operation the patient is given the routine premedication of omnopon 2/3 grain and scopolamine 1/150 grain. When he is brought into the theatre or anaesthetic room he is put into the lateral decubitus, and the skin and the tissues down to the spinal column are infiltrated before the spinal needle is inserted into the third lumbar space. This needle is one of fine calibre, and the fluid is allowed to drip from it in order to ensure that it has penetrated to the spinal theca; the percaine solution, having been heated to blood heat, is slowly introduced with a syringe into the canal. The quantity varies with the upward extent of analgesia required. For low abdominal operations 10 c.cm. are necessary, for medium 12 c.cm., and for high 15 or 16 c.cm. After the needle has been withdrawn the patient is immediately turned on his face, and the table tilted into 15 degrees Trendelenburg. After six minutes he is turned over on to his back, and the operation proceeds. No further anaesthetic is necessary, but if for any reason it is desired to have the patient unconscious gas and oxygen may be given throughout the operation. When the operation is over he is kept in the slight Trendelenburg position for some hours in order to avoid the complications that may occur after any spinal anaesthetic. This is effected by raising the foot of the bed on high blocks for eight hours, then on low blocks for eight hours. The patient is finally kept supine for the same length of time, after which he may be slowly raised into the sitting position. In cases of necessity Fowler's position may be assumed gradually three hours after the injection.

Etherington Wilson's technique differs from that described above in that the injection is given in the upright sitting position. After the commencement of the injection this position is maintained for twenty-five seconds to produce anaesthesia up to and including the perineum and hypogastrium, for thirty seconds for the level of the umbilicus,

and for forty seconds to reach the epigastrium. The patient is immediately laid on his back in the 15 degrees Trendelenburg position, and the operation may begin at the end of seven minutes. This technique is the method of choice for pregnancy, for patients with large abdominal tumours, and for similar cases.

Intravenous Injections

This is the third and most recent method of producing a general anaesthesia. I have been using evipan over a period of twelve months, and for upwards of 1,000 cases. It may be used as a form of premedication, followed by either gas and oxygen or a spinal anaesthetic, or it may be used by itself as a general anaesthetic. There are two distinct types of case for which this anaesthetic may be employed.

SHORT ANAESTHESIA WITH EVIPAN

It is useful for operations in the out-patient department, where anaesthesia is only required for a moment or two. No premedication is necessary or desirable here, and only the minimum dose of evipan should be used. There is no need to withhold food, or to wait until three or four hours have elapsed since the last meal. The dose of evipan injected intravenously is from 2.5 to 5 c.cm. The operations which are commonly performed under this minimum dose are: dental extractions, the opening of abscesses, whitlows, etc., the removal of nails and specimens for biopsy, and any similar procedures in out-patient work where anaesthesia from thirty seconds to a few minutes is required. The operation should be commenced immediately the patient is unconscious, and everything should be quite ready before the injection is begun. If no more than the minimum dose is injected the patient is "round" in two or three minutes. He is allowed to rest on a couch or chair for from twenty to thirty minutes, and is then able to go home, preferably with attendance. If, however, more than the minimum dose has been injected a longer period must be allowed for recovery, and it will be necessary to have a friend to see him home safely.

Technique

The first 2.5 or 3 c.cm. is injected fairly quickly (five to ten seconds), and a pause of about thirty seconds (which is the normal time for the complete circulation of the blood) is then allowed. At the end of this time unconsciousness usually takes place. If not, a further 2 to 3 c.cm. is injected, and the minor operation is performed. The patient regains consciousness almost as quickly as he went under. If the injection is steadily continued after the first 2 or 3 c.cm. without any pause, a further 3 or 4 c.cm. will be injected before unconsciousness supervenes. This means that the patient gets double, or more than double, the minimum dose; unconsciousness lasts from ten to twenty minutes, a longer time is needed in the recumbent position for recovery, and the patient is more apt to pass into a sort of drunken state, and for a longer period, than if a smaller dose had been used.

EVIPAN ANAESTHESIA WITH PREMEDICATION

For in-patients evipan may be combined with premedication, so that before the patient is removed to the theatre complete oblivion, or at any rate somnolence, is produced to eliminate all psychic shock, permit any necessary preparations for the operation to be made without the patient's knowledge, and provide a peaceful sleep for some hours afterwards.

In order to ensure successful anaesthesia with evipan I use my routine premedication method of omnopon and scopolamine. This produces a satisfactory state of somnolence. The Hoffman-La Roche preparation, containing omnopon 2/3 grain and scopolamine 1/150 grain, I

have found most reliable for all patients between the ages of 16 and 70. Half this dose may be given to a large child or elder person. The preparation contains the laevorotatory scopolamine, which is the sedative alkaloid of hyoscyne, and does not include the stimulating dextrorotatory alkaloid. The injection is given one hour before the operation. The patient is then left quietly in a darkened room, or with a bandage round his eyes, in order to encourage sleep. The majority of patients are quite unconscious by the time they reach the theatre. Among private patients, when this state of affairs has been promised and is not attained, an injection of evipan is given one hour after the premedication, with the patient still in bed. He is then transported to the operating table, and a further injection of evipan is given for all but short operations.

DOSAGE AND GENERAL INDICATIONS

For minor operations upon in-patients a full dose of evipan (1 gram dissolved in 10.5 c.cm. sterile water) may be given without premedication, or combined with omnopon and scopolamine, one hour before. Evipan is without doubt very useful in cases of manipulation of the back, shoulder, knee-joints, or ankle-joints; complete relaxation is obtained, especially if omnopon and scopolamine have been given previously. For major operations, as I have already said, evipan may be used as a total, as well as a basal, anaesthetic. When used as a total anaesthetic the full dose may be repeated as often as required during the operation. For a strong, healthy young adult it has often been found necessary to repeat the full dose within a few minutes. But in younger and older patients it seldom becomes necessary under twenty to thirty minutes. The maximum number of times I have repeated the injection has been four, over a period of two hours.

As already stated, evipan may be used as a basal narcotic, preferably after omnopon and scopolamine; it may be given to render the patient unconscious before being taken from his bed, or for the injection of a spinal analgesic, or for the passage of an endotracheal tube. As a subsequent inhalation anaesthetic, nothing should be given but nitrous oxide and oxygen, the use of either chloroform or ether being avoided, these drugs not only being dangerous in themselves, but notoriously more so in combination with barbiturates. For example, for such operations as gastrectomy, cholecystectomy, hysterectomy, rectectomy, etc., evipan is frequently used after the premedication, a spinal anaesthetic then being administered: and later, in order to maintain unconsciousness throughout the whole period of operation, the dose of evipan is repeated or anaesthesia is continued with nitrous oxide and oxygen by means of the McKesson apparatus. Where a closure of the upper air passages is indicated, anaesthesia should be produced with evipan, and the intratracheal tube passed transnasally, anaesthesia being continued if and when necessary with more evipan or with N_2O and O_2 .

CONTRAINDICATIONS OF EVIPAN

There are certain contraindications to the use of evipan. It is metabolized in the liver very rapidly, and any gross disease of this organ, or the presence of jaundice, should definitely preclude its employment. General feebleness of the patient and low blood pressure, or low Moot-McKesson ratio, are also contraindications, because evipan does cause a definite, though temporary, fall in blood pressure. Again, it is felt that the upright position is another contraindication to the use of large doses of the drug, on account of this sudden fall in blood pressure.

It is therefore advisable that for dental extractions, etc., the patient should be lying down and not upright. (Lack of available space only applies to institutions where large numbers of cases are to be dealt with, and where sufficient room is not available to allow all patients to recover sufficiently to be able to proceed home. This question does not arise in the in-patient department.) Lastly, it is not advisable to give evipan to patients who have already had other barbiturates as premedication. Slow recovery and prolonged depression of respiration and blood pressure have only occurred in patients who have been given nembutal previously.

SOME DANGERS AND DIFFICULTIES

The Jaw.—In from fifteen to twenty-five seconds after the administration of evipan the patient is completely unconscious, and the first phenomenon to be observed is the dropping of the jaw. An attendant should always be present to see that this is not allowed to happen, and to maintain an adequate airway. Dropping of the jaw may be partly avoided by the patient's head being to one side, and the jaw is more easily supported if the patient has a small dental prop between his teeth. The airway is always completely maintained if a rubber (Phillips's) airway is inserted into the pharynx immediately unconsciousness takes place. It cannot be too strongly emphasized that the danger of allowing the jaw to fall and the tongue to drop back, thereby causing obstruction of the air passage, is a most serious one, and must never be allowed to occur. Evipan should therefore only be administered single-handed in the most unusual circumstances.

Blood Pressure.—A fall of some 20 per cent. or even more in the blood pressure always occurs. This is both systolic and diastolic. In my experience it has produced no deleterious immediate effects or after-effects, but I have not used evipan for patients with a low blood pressure, as trouble can be expected, especially if old and feeble persons are anaesthetized in the sitting posture.

Respiration.—A similar depression of respiration occurs, but again this is very transient, and provided the airway is maintained should cause no alarm.

Restlessness and Twitchings.—Slight involuntary movements and tremors occasionally take place. These are never gross, but are a little disconcerting to the beginner working with evipan. They very seldom happen if the premedication described above has been given beforehand, and they are readily overcome by a further injection of from 5 to 10 c.cm. of evipan.

Signs of Drunkenness.—Patients who have been given more than the minimum dose and allowed to go home when they had apparently recovered have been known to exhibit signs of drunkenness in the street. If more than 3 c.cm. have been given, ample time must be allowed for recovery to take place, and a comrade should see the patient home.

After-effects.—I have had no deaths following the use of evipan in over 1,000 cases. Careless nursing and failure to maintain an airway after the patient's return to bed have given me some minutes' anxiety in a few cases in my earlier experience. No pathological process appears to have been aggravated, though restlessness has been very marked in some dozen instances—all, I think, in the highly strung type. A definite though very small proportion of patients are found to vomit after the use of any opium derivative. I feel that the very small proportion, about 1 per cent., of patients who have vomited after evipan is not greater than the proportion who vomit after the use of an opiate alone. No case that has

had evipan alone—that is, without premedication—has vomited.

Antidotes.—The antidotes for evipan do not differ from those for any other form of general anaesthetic, nor are they more often needed. During collapse coramine is by far the most reliable drug for general purposes, but it must be used liberally; 5 c.cm. should be the average dose, and 10 c.cm. may be given quite readily for any general collapse. Recently I have been trying the effect of icoral and picrotoxin, which appear to be even more potent general stimulants than coramine. For simple respiratory failure from whatever cause alfalobeline is the only drug causing direct respiratory stimulation. A dose of 3/20 grain, or even twice that amount, may be given intravenously for rapid action, or, for slow action, subcutaneously. The other direct respiratory stimulant is carbon dioxide. It should be given, if possible, under pressure, in a mixture consisting of 7.5 per cent. carbon dioxide with oxygen. Cylinders of these gases in the above proportions should be in every operation room and every recovery room. Incidentally, they should be carried on every fire-engine, and found in every first-aid box—especially on river banks and in lifeboats. I regret to say that there are, as yet, very few doctors' surgeries or nursing homes which have them.

Conclusions

I believe the best modern anaesthetic to be nitrous oxide and oxygen, which is administered most successfully by the McKesson apparatus, without the use of ether or chloroform, and which is best preceded by omnopon and scopolamine as premedication. Where it is essential that no drop in blood pressure should occur, nitrous oxide and oxygen is the general anaesthetic of choice. Similarly, where instantaneous recovery is desirable it is extremely valuable. This form of anaesthesia allows full premedication, so ensuring a complete absence of psychic shock; it is not followed by vomiting, and it does not aggravate any pathological condition present.

Surgical cases of already established pulmonary disease can be dealt with without any form of inhalation anaesthesia, and for many of these evipan has proved ideal. No expensive or heavy apparatus is required, though it is strongly advisable always to have at hand a positive pressure apparatus for the administration of CO₂ and O₂, or nitrous oxide and oxygen. It must be remembered that, except in a few centres, it is difficult to get a good nitrous-oxide-oxygen anaesthesia, or even to avoid ether or chloroform. Chloroform, I believe, should never be used at all, and ether only in extraordinarily rare circumstances.

The council of the Royal Sanitary Institute, London, has decided to offer for award annually a challenge shield for the best celebration of Health Week in the Empire, outside the British Isles. In view of the great interest which was taken by the late Professor Bostock Hill in the Health Week movement from the date of its inception, the challenge shield will be known as the "Bostock Hill Memorial." The date fixed for Health Week this year is October 7th to 13th, and over-seas centres wishing to enter the competition for the shield must submit, by December 31st, 1934, full programmes and reports of any celebration held.

The Istituto Ortopedico Rizzoli in Bologna announces a competition for the prize Umberto I for the best orthopaedic work or invention. This prize of 3,500 lire will be awarded according to the decision of the Provincial Council. Italian and foreign doctors may take part in the competition, which closes on December 31st, 1934. Copies of the regulations may be had from the president of the Rizzoli Institute, Bologna.

ON THE NATURE OF HIGH ARCHED
PALATE

BY

O'C. O'SULLIVAN, M.C., M.B., B.Ch.

ASSISTANT SCHOOL MEDICAL OFFICER AND INFANT WELFARE MEDICAL
OFFICER, NORTHUMBERLAND COUNTY COUNCIL

In the course of an investigation as to the evidence of vitamin D insufficiency among children one of the most constant and striking features was the frequency of the presence, in varying degrees and a variety of forms, of high arched palate. Most of the explanations of this phenomenon which have been put forward¹ assume the action of some forces which, in conjunction with softening of the bony tissues, press the hard palate upwards in the centre, whilst at the same time laterally compressing the alveolar arch. Certain observers (G. C. M. M'Gonigle, J. C. Brash²) have questioned the feasibility of these explanations. It is not difficult to see, when the general architecture and structure of the facial bones is considered, that a very much greater force would be necessary than could be derived from the neighbouring muscles. The feeble action of the buccinators, for example, would be more than antagonized by the action of the tongue, which tends to press the palatine arch outwards as well as pushing the roof upwards. Again, the type of deformity usually found in a very large series of cases did not correspond to that which would be expected as the result of forcible deformation of the palate. Direct inspection with a well-illuminated speculum failed to reveal any encroachment upon the nasal fossa, even in cases of extremely narrow highly arched roof; nor was there observed any cockling up or marked deviation of the septum nasi. Convincing evidence of lateral compression is likewise absent. If the lips are well retracted it will be seen that there is no real narrowing of the outer circumference of the alveolar arch, and that the teeth do not point inwards and downwards, as would be expected under the influence of inward pressure on the alveolar arch.

As a result of the examination of a series of children from birth up to the completion of the first dentition, and also of the children at school medical inspections, an alternative explanation suggested itself—namely, that there is actually no elevation of the palate, the apparent height of the roof being entirely due to abnormal downward elongation of the alveolar process, the narrowing being due to the inward expansion both of the alveolar and, to a varying extent, of the palatine processes. The number of children examined at school, extending into thousands, ensured that every variety of buccal cavity would be included in the investigation, which extended over a period of three years.

The normal course of development of the roof of the mouth appears to be somewhat as follows. At birth the roof of the mouth generally shows a slight degree of cupping, resembling somewhat a segment of a dinner plate. After a varying period—usually about one to three months—the anterior edge of the alveolar process becomes markedly enlarged in the centre, at a place corresponding to the two centres of ossification of the premaxilla and maxilla. This enlargement increases and spreads backwards, and, as dentition progresses, the descent of the teeth and the deepening of the alveolar arch result in the formation of a moderately high, rounded arch by the middle of the third year. At the commencement of the second dentition this condition appears normally somewhat accentuated, the alveolar arch now containing the twenty erupted deciduous, as well as the fourteen calcified crowns of the permanent set. The size and rate of growth

of the alveolar process is thus greater during the period of dentition, particularly in the vertical direction, than the lateral growth of the palate. During the second dentition, with the loss of the deciduous and the gradual descent of the permanent teeth, an approach is made to the adult type of flattened wide roof, with short, gently sloping sides, the growth of the palate being now relatively greater than that of the alveolar process (and arch).

This is roughly the normal course of events. In certain cases, however, the thickening of the premaxillary area is greatly exaggerated, forming a distinct swelling, marked off on either side from the rest of the maxillary edge by a U-shaped vertical groove. This hyperplasia may remain confined to the region of the incisor and canine teeth or may spread a varying distance along the alveolar arch, resulting in exaggeration of the normal vaulting. This becomes further accentuated during the second dentition, when thickening of the arch becomes a prominent feature, especially if the descent of the permanent teeth is obstructed by the retention of the stumps and fragments of the deciduous teeth (removal of these leading to marked diminution of the thickening). Thickening of the buccal surface of the palatine process is also frequently present in a marked degree.

The various types of deformed roof described in the literature of the subject depend chiefly upon variations in the relative degrees of downward elongation and thickening of the alveolar processes, and also upon the degrees of thickening of the palate bones. For example, when the arch is much thickened in front and tapers away behind we have the well-known A-shaped roof. Great hypertrophy of both palate and alveolar process brings about obliteration of the normal angle of the roof, and produces the saddle-shaped type of roof, the latter resembling the under surface of a saddle. With the progress of dentition the bony hyperplasia diminishes and deformity becomes less marked.

The bony hyperplasia differs in no way from the thickening of the cranial bones in rickets, and, like it, commences at the centres of ossification, is there more marked, and often remains limited to that region. Of the children investigated 80 per cent. showed unmistakable evidence of previous rickets, and the diet was notably poor in foods containing calciferol. The tendency for the deformities to become modified with age has also been noted, as is the case in rickets.

The conclusion drawn from the investigation is that there are two distinct varieties of high arch: (1) The *congenital*, which is a persistence of a certain stage of foetal development. In this type there is actual elevation of the floor of the nasal fossa, which slopes up and inwards to meet the nasal septum. (2) The *acquired* variety described above, in which there is no actual elevation of the roof of the mouth, the *apparent* elevation being due to hyperplasia of the alveolar and palatine processes, and is probably of a rickety nature. The two types may coexist.

As the acquired variety is very widespread, at any rate in this district—20 per cent. of "infants," 30 per cent. "immediates," and 15 per cent. of "leavers" among school children, showing *marked* deformity—it is only to be expected that it will be found associated with other conditions, such as adenoids, mouth-breathing, nasal obstruction, and mental deficiency, with which it appears to have no aetiological connexion.

I am greatly indebted to Dr. G. C. M. M'Gonigle for his criticism and help in drawing up this memorandum.

CLINICAL MEMORANDA

Clinical Memoranda

AN UNUSUAL CASE OF HYPERPYREXIA IN MALARIA

High temperatures in single or double infections with malaria may possibly occur and escape observation if the readings are taken at too long intervals. Observations on such patients should be made with special highly calibrated thermometers—if such instruments are procurable—and at short intervals. The results might prove of considerable interest. It must be a rare occurrence for a patient to sustain a hyperpyrexia, such as is here recorded, and live.

On January 11th, 1934, a man was admitted to the Hospital for Tropical Diseases under the care of Dr. A. E. Horn. His history was as follows. Born in England, he had resided in Nigeria since 1928, except for periods of furlough at home. In Nigeria he had had five attacks of malaria. He returned home in November, 1933, and on December 9th, while in London, he had another attack of malaria, which developed into blackwater fever, and from this he was recovering when admitted into the Hospital for Tropical Diseases.

For twelve days after admission he showed some swing of temperature from 97° to 99.4° F.; the spleen was palpable, but no malarial parasites could be found in the blood. On January 23rd, a rigor occurred, and the temperature reached 102° , but no parasites were found; the next day the temperature subsided. On February 7th the temperature again shot up to 101° , but on this occasion the blood followed malignant tertian malaria to be present. This was followed on February 9th by another rigor, which commenced at 7 p.m., and blood slides taken immediately showed, in addition, parasites of benign tertian malaria. At 8.15 p.m. the temperature had risen to 107° (pulse 104, respirations 24), and orders were given for it to be recorded every fifteen minutes. At 8.30 p.m. the thermometer showed 110° and orders were given for it to be recorded every fifteen minutes. At 8.40 p.m. the mercury reached and passed (pulse 110, respirations 24), so another thermometer was at once obtained. At the limit of the calibration above the 110° mark, the thermometer showed some calibration above the thermometer, while on the second thermometer used (which had been selected as it showed some calibration above the 110° mark), the mercury reached the top of the instrument level with a mark estimated at 115° . Orders were at once given to sponge the patient, but before this was done the temperature showed a fall to 105.4° (pulse 104, respirations 24). Sponging was withheld, and the subsequent readings were: 10 p.m. 104° (pulse 122, respirations 24); 10.25 p.m. 105° (pulse 138, respirations 26); and at 10 p.m. 104° (pulse 122, respirations 24).

During the whole period of the hyperpyrexia the patient's condition was good; he was quite rational, no cerebral symptoms were present, and there was no loss of consciousness. The pulse was soft and regular, and showed no marked acceleration until 9.25 p.m., when it quickened to 138. Respiration was regular all through the period, but at the peak was "panting" in type, expiration ending with a soft grunt, while the patient complained of a sensation of compression "like a weight" on his chest. A feeling of nausea was present throughout, but vomiting only occurred once, just after 8.55 p.m. There was no sweating until after 9 p.m., and then only to a slight degree. The urine showed no return of "blackwater." Treatment with atabrine was at once instituted, and no subsequent hyperpyrexia occurred. The patient is now convalescent. All temperatures were recorded in the mouth, and it is to be regretted that neither rectal nor axillary readings were taken.

The original thermometer was continued in use in the wards, and its readings have excited no suspicion of inaccuracy. The second thermometer was submitted to the experts at the National Physical Laboratory at Teddington, it having been laid aside at once with the mercury still showing the height recorded, estimated at 115° F. Examination disclosed a flaw in the bulb, which in the expert's opinion, was the type of flaw that would follow great expansion of the mercury consequent on

exposure to too high temperature, rather than one consistent with rough usage. There was no evidence of defect in the instrument before use.

That the patient sustained a temperature exceeding 110° F. is undoubted. He had been accustomed to his temperature being taken, and had no idea that it was higher than usual during this particular period, so the suspicion of biting both thermometers can be eliminated. No hot drinks were given, and all other sources of possible error have been investigated without result. It is unfortunate that the defect in the thermometer precluded the accurate estimation of the temperature attained being made at the National Physical Laboratory.

We are indebted to Dr. A. E. Horn for permission to publish the details of the case.

House-Physician, Hospital for
Tropical Diseases, London.

EXTREME HYPERPYREXIA IN MEASLES

In most respects this case seems to conform with the toxic type in which Ker's *Manual of Fevers* states: "The patient succumbs to the virulence of the measles toxins quite apart from complications. . . . Death occurs on the second or third day of eruption, and the temperature reaches hyperpyretic levels towards the end." Yet it seems difficult to correlate the apparently normal course for the first few days of the illness, during which normal sweating took place, and the terminal hyperpyrexia, in which it seemed impossible to produce sweating, unless one supposes that the toxæmia had completely disorganized the heat-regulating centre. It must be most exceptional for any toxin to cause such extreme hyperpyrexia as 109.2° F.

A puffy, underweight infant, aged 3 months, developed measles on January 16th, 1934, the rash appearing on the 18th. The illness ran a normal course, apparently, and on the morning of the 20th the fever had subsided after a profuse perspiration and the rash was fading. At about 6.30 p.m. the child seemed ill and feverish again, and had a convulsion.

On examination at 8 p.m. on January 20th the child was having a convulsion, which lasted two or three minutes. He was greatly overclothed, and in an overheated room. He was obviously very ill. The temperature in the axilla was at the incredible level of 109.2° . Every care was taken to exclude fallacies in recording the temperature. The pulse was 140. Respiration could not be counted accurately, but did not appear to be excessively rapid. The child was immediately put into a lukewarm bath, and after about fifteen minutes the temperature fell to 104° , but the skin was still dry and burning, and within a few minutes the temperature had risen to 104.4° . He was troubled with mucus in the throat, but could not cough properly. All the physical signs of meningitis were absent, and there were no signs of bronchopneumonia. He could suck and swallow a little. Within the next three hours he had two more convulsions, and two lukewarm baths which relieved him but failed to make him sweat.

At the time of the second examination—at 1 a.m. on January 21st—the temperature was 106° , pulse much more rapid and weak, respirations rapid. There were short intervals of sleep with quiet, easy breathing, alternating with periods of distress with noisy breathing and attempted coughing. The skin was still hot and dry. The child was too collapsed to permit of a long lukewarm bath. During the previous two hours there had been repeated passage of mucus, slightly tinged with faeces.

There were no more convulsions, and the child lapsed into coma and died about 2.30 a.m., eight hours after the first convulsion.

Chagford, Devon.

A CASE OF SEVERE ANAPHYLAXIS IN GENERAL PRACTICE

The rarity of severe anaphylaxis is, I believe, still considerable, in spite of the many thousands of people who receive injections of serums, and in general practice, where comparatively fewer serum injections are given, this very grave complication must be rare indeed. The following case would appear to be worth recording on account of its severity, rarity, and recovery.

The history of the case begins with an acute infection of the fauces and palate, with much oedema, particularly of the uvula, and a profuse, slimy exudate. The case occurred during an epidemic of sore throats in which the causative organism had almost invariably been a streptococcus, usually of the haemolytic variety. After consultation with my partners, and in view of previous successes with this treatment, it was decided to give an intramuscular injection of antistreptococcal serum.

After inquiries had been made from the patient as to whether he had previously been given antitoxin and a negative answer received, 10 c.cm. of streptococcus antiserum were injected into the gluteal muscles at 8 p.m. on December 29th. About a minute afterwards the patient complained that he was feeling queer and going blind. In a few seconds the face became engorged and cyanosed, there was frothing at the mouth, loss of consciousness, and finally cessation of breathing. An intramuscular injection of 10 minims of liq. adrenalin. hydrochlor. was given immediately, and artificial respiration started. At this time the eyes were upturned and the pupils widely dilated; no pulse was palpable at the wrist. A cylinder of oxygen was sent for, and about ten minutes after the onset of the attack O_2 and CO_2 were being administered in conjunction with the artificial respiration, which had been continuous.

At 8.15 an intramuscular injection of 1/2 c.cm. of pituitrin was given; this was followed by an injection of camphor in oil. About five minutes later (at 8.20) the patient began to take deep, sighing respirations, and after a few moments to breathe spontaneously, though slowly, and artificial respiration was discontinued. As the patient was still cyanosed the administration of O_2 was continued. Another injection of 5 minims of adrenaline was given at 8.30. At this time the pupils had become contracted, and there were flickering movements of the eyelids. The radial pulse was still undetectable, and noisy breathing and crepitations masked any sounds at the apex beat. The patient was still unconscious, and there was incontinence of urine and faeces. Half an hour later (at 9 o'clock) the radial pulse became just palpable at a rate of 134 beats per minute. The patient passed blood and mucus per rectum at 9.30.

At 10.45, as the pulse was only palpable for short periods, another 1/2 c.cm. of pituitrin was injected. At 11.20 1/6 grain of morphine was given subcutaneously, as the patient was becoming very restless. Blood and mucus were again passed per rectum at 11.40, after which the patient became quieter and lapsed into a deep sleep until 12.20 a.m. The pulse rate had now fallen to 118 beats per minute, but was still very feeble. For the first time, at 1.15, the patient vomited, and 10 minims of adrenaline were injected. The pulse at 2.30 was 109 and at 3.30 108 beats per minute. At 5.30 the patient again vomited slightly; the pulse was then 106. The temperature at 8.30 was 99°, and the pulse was 100. By 9 o'clock this had dropped to 98°. At this time there was no recollection of the incidents of the night, or of the original injection which had caused all the trouble.

On this day, December 30th, at about 5 p.m., a few small patches of urticaria appeared on the face, and an hour later the patient passed about a pint of urine, which contained protein and a trace of sugar. This was the first passed since the incontinence of the early part of the attack. The urticaria spread, and at 8.15 the upper lip became much swollen, and the patient again passed mucus and blood per rectum; accordingly another 5 minims of adrenaline were injected. By 10.30 the lip had regained its normal size, and the urticaria had disappeared. About this time another half a pint of urine was passed. During the night there were profuse sweats, and small quantities of urine were passed twice.

On December 31st the patient was still unable to remember any of the incidents of the illness, or to retain in his mind anything that he was told for more than a few minutes, but the questions that he asked indicated that his mind was active. The pulse was now of full volume and normal pace and rhythm. The apex beat was in its normal situation, and no abnormal physical signs were found in the chest or abdomen. The subsequent history of the case is one of progressive recovery. The gastro-intestinal symptoms, though decreasing, persisted for several days, but there was a return of swelling of the upper lip five days after the original attack. This quickly responded to adrenaline. The patient returned to work on January 30th, and although the mental processes are normal there is no memory of events immediately preceding the attack and for a day or two afterwards.

Since the patient's return it has been elicited that seven years ago he had a severe haemorrhage after tonsillectomy and was given haemoplastin. This would appear to have been the sensitizing agent. It is interesting that after the lapse of such a time the patient should have been so sensitive to horse serum. Other points are the rate and order of return to normality of the various systems, and the recurrence of the milder forms of serum poisoning for several days after the attack. The dramatic effects of the administration of adrenaline on the milder symptoms suggest that much larger quantities of this substance could have been given in the first instance and repeated more frequently.

West Malling. H. R. R. MAVOR, M.R.C.S. L.R.C.P.

AN UNUSUAL CASE OF HAEMATOCOLPOS

The case to be recorded is of interest for two reasons: (1) the age of the patient; and (2) the fact that she gave no history of any previous symptoms that might act as a guide to her condition. On this occasion an attack of appendicitis proved a blessing in disguise.

HISTORY OF CASE

On December 19th I was called to see a young Jewish schoolgirl, aged 12 years, who was suffering from severe abdominal pain. History and examination suggested an acute appendicitis; the temperature was 101.4° F.

On December 20th the patient felt better, but experienced the sensation of a lump in the abdomen; this was difficult to examine on account of the general tenderness and the nervousness of the child, but it was certainly evident, and seemed like a faecal mass. By this time the temperature had dropped to 100° F.

On December 21st an enema was administered with a good result. Examination elicited a movable tumour at about the level of the umbilicus. It was rather hard, rounded, and tender on pressure, and appeared to be about the size of a tangerine orange; otherwise the patient was better.

On December 22nd the patient had had a restless night, with frequent attacks of intestinal colic, and appeared anxious and distressed. The temperature was normal, but I urged operation.

On December 23rd I performed a laparotomy, making a midline incision from the umbilicus downwards. On entering the peritoneal cavity a slightly congested normal uterus presented itself at the upper angle of the wound. The vaginal cavity was greatly distended and fluctuating, so I realized I was dealing with a case of haematocolpos. I then isolated and removed the appendix, which was considerably swollen and inflamed. This done, and having sutured the abdominal wound, I proceeded to examine the vagina, where I found a bulging, bluish membrane of a resistant nature, requiring quite an amount of force to cut through with a knife. When I had perforated this membrane the best part of a quart of menstrual blood drained away, and in a couple of days the patient experienced complete relief of all her symptoms. She made an uneventful recovery, and at the end of a fortnight I made a vaginal examination and found the uterus in its normal position, with an opening in the hymen that would admit my index finger.

Hove.

J. G. HAYES, L.R.C.P.S.I.

ALLERGIC SENSITIVITY

The circumstances of the reaction described below would appear to be unique and therefore to warrant recording.

An apparently healthy girl, aged 23, a probationer nurse at the Coventry City Isolation Hospital, was Schick-tested on January 9th, 1933, and showed a strongly positive reaction. Accordingly injections of toxoid-antitoxin (T.A.M.) were given on February 3rd, 10th, and March 10th. On September 13th, 1933, she was Schick-tested a second time, and the resultant reaction was deemed to be mildly positive. A further series of toxoid-antitoxin injections were given on October 14th, 21st, and November 23rd.

A third Schick test was carried out on January 5th, 1934, and some twenty minutes after this intradermal injection of 0.2 c.cm. of test toxin the nurse complained of feeling very ill, with pains in the back and cutaneous irritation over the whole body. A copious serum rash of the urticarial type made its appearance, and for some time there was swelling of the eye-lids. The rash faded from the face after an hour, and from the rest of the body, save on the "test" arm, a little later. On the "test" arm the following day there remained a brawny swelling at and about the site of the injection, with a surrounding circle of scarlatiniform erythema some three inches in diameter. Several days later the skin of this region remained brownish red, scaly, dry, and tender until finally the arm cleared up. The "control" arm showed no reaction.

It appears that despite the violent reaction to the third Schick test the nurse was then in fact Schick-negative. A specimen of blood was taken on February 13th, 1934, and was submitted to Dr. R. A. O'Brien (of the Wellcome Research Laboratories), who kindly undertook to titrate it for diphtheria antitoxin. Dr. O'Brien's subsequent report stated that the nurse had 1/10 of a unit of antitoxin, and that she should therefore have been Schick-negative.

It is difficult to explain the generalized reaction resultant upon the third intradermal injection of the test toxin, for no similar reaction followed the first or second test injection, nor was there any reaction following the six immunizing injections. At the same time as this nurse received her third injection, three other nurses were tested with material from the same batch of toxin, and showed no uncommon reaction. There was no question of faulty technique. The nurse in this case did not appear in any way an unusual subject, and she had no past history of asthma, hay fever, migraine, or the like. The persistence of the scaly condition of the skin would appear completely to remove the case from the range of "hysterical" phenomena.

It may be that the first and second injections of test toxin had together conferred a hypersensitivity to some specific element contained only in the test toxin itself. If sensitivity had been thus acquired the case appears as a form of anaphylaxis. Alternatively, it may be that the case was a strange form of allergy or "inborn" sensitivity. Professor Langdon Brown has admirably described the latter as a chemical idiosyncrasy which exemplifies the variation in the response of different individuals to similar stimuli. Whether the anaphylactic or the allergic theory is pursued in this case, it is indeed extraordinary that the nurse had not shown an abnormal reaction to any of the eight previous test and immunizing injections.

Our thanks are due to Dr. R. A. O'Brien, to whom particulars of the above case were submitted, for his helpful suggestions. He informs us that the batch of Schick toxin associated with the case was a large one, and has been used in many hospitals. He has never met a similar incident connected either with this batch of toxin or with any other, and is unable to trace a like case in the literature.

Coventry.

Reviews

THE CANCER PROBLEM

The fact that cancer is much more frequent among civilized than savage races, and is increasing in frequency, is one of the outstanding features of the disease. Two books on the cancer problem have recently appeared which deal with this question and are of particular interest in that they reach the same conclusion by diametrically opposite routes. Mr. J. P. LOCKHART-MUMMERY, who has acted for eleven years as editor of the *Annual Report of the British Empire Cancer Campaign*, and has therefore been in close touch with the results of scientific research, approaches the subject mainly from the experimental side in his book on *The Origin of Cancer*.¹ Mr. HASTINGS GILFORD, on the other hand, in a brochure on *The Cancer Problem and its Solution*,² rejects in toto the vast mass of information that has emanated from laboratory experimentation, which he considers has merely served to obscure the problem. He relies solely on the clinical and post-mortem observations which have been made during the last hundred years.

Mr. Lockhart-Mummery's conclusion is that civilized man, not having been subject to the law of natural selection for some thousands of years, has gradually suffered a diminution in the natural stability of his cell nuclei, and has acquired an abnormal tendency to gene mutation, which the author regards as the essential cause of cancer. Naturally, as long as present conditions persist, this degradation will continue to progress and the disease increase in frequency. Mr. Hastings Gilford comes to very much the same conclusion, expressed in somewhat different terms. He considers that our civilization makes for degeneration; that an ever-increasing growth of national degeneracy is now displaying itself in our nation; that race suicide may almost be said to be in sight; that everywhere around us, in our hospitals and charitable institutions, movements are at work which act benevolently on the individual but malevolently on the race; that sentimentality prevails over common sense. The effect of this general degeneration is, he considers, to produce a degradation of cell structure, a precancerous condition in which the cells, if left to themselves, tend to die out, but under suitable stimuli take on the abnormal cell proliferation obtaining in cancer. In this way are explained the prevalence of cancer and its continued increase in frequency. It should be said that Mr. Lockhart-Mummery's book contains much more than the discussion of this question. It gives a detailed and very interesting description of the theory of which he is the author—namely, that all the characteristic features of simple and malignant growths may be readily explained on the supposition that tumours are the result of the mutation of one or more of the constituent genes of the chromosomes of somatic cells.

OPERATIONS ON CHILDREN

No one book can cover the entire field of surgery, so that each author must seek for some point of division that will enable him to decide what material to include and what to leave out. Certain ages, certain regions, certain infections, are all well recognized as useful boundaries to the extent of a book. But the boundary that M. FÉVRE has chosen in his *Chirurgie Infantile d'Urgence*³—that of

¹ *The Origin of Cancer*. By J. P. Lockhart-Mummery, M.A., M.B., B.C., F.R.C.S. London: J. and A. Churchill, 1934. (Pp. 159; 29 figures. 10s. 6d.)

² *The Cancer Problem and its Solution*. By Hastings Gilford, F.R.C.S. London: H. K. Lewis and Co., Ltd. 1934. (Pp. 59. Cloth, 2s. 6d.; paper, 1s. 6d.)

³ *Chirurgie Infantile d'Urgence*. Par M. Févre. Paris: Masson et Cie. 1933. (Pp. 452; 110 figures. 70 fr.)

urgency—is surely one of the least satisfactory. To take only a few of the subjects treated—hernia, mastoiditis, empyema, or the malformations of the rectum: in all of these the urgent cases shade into the non-urgent, and both groups are governed by the same fundamentals of anatomy, physiology, pathology, and technique. The merit of any work depends on the setting out of these fundamentals, and once they are set out the question of urgency becomes comparatively unimportant.

This somewhat captious criticism of the plan of the book is really a tribute to the excellence of the material arranged upon that plan. M. Fèvre follows closely throughout the teaching of his revered senior, Professor Ombredanne, whose vast and authoritative work on the surgery of children was lately reviewed in these columns. As might be expected from one taught in this school, his conclusions are clearly set down and admirably arranged under headings in a way that might with advantage be copied in this country. There is also a good deal to be said in favour of the French custom of trying to reduce the essentials of a condition to diagrammatic form, as opposed to the English one of giving photographs of its external appearance.

Particularly interesting and instructive sections are those on appendicitis, on acute inflammations of the testicle, and on pericarditis. Many in this country will agree with the author that general anaesthetics and rib resections are unnecessary and dangerous for the empyemata of children, and with his recommendation that the lateral sinus (why not also the middle cranial fossa?) should be inspected as a routine in operations for mastoiditis. To help in the notorious difficulties of abdominal diagnosis in the young he recommends exploration through a "button-hole" incision in the peritoneum made under local anaesthesia; and to ward off threatening ischaemia of the forearm advises incision of the aponeurosis confining the muscles.

Less admirable are his figures showing ligation of the splenic pedicle *en masse*, and the omission of warning against the tendency to stenosis following the high tracheotomy which he advises: the tannic acid treatment of burns has apparently yet to penetrate to France. On the whole, however, this is a book to the writing of which much experience, thought, and hard work have gone; and it is worthy of careful study by all interested in the surgery of the young.

OCCUPATIONAL SKIN DISEASES

A pathetic interest attaches to the appearance of a new edition of ROBERT PROSSER WHITE's well-known treatise on *Occupational Affections of the Skin*,⁴ for it was but a day or two after he had revised the final proofs that he died. This subject, to which Prosser White devoted his life, has grown more and more in importance with the progress of modern industry, and this book has necessarily grown with it. Nevertheless the fourth edition, although including a considerable amount of new material, has been prevented from exceeding the size of the third, which appeared in 1928, by the use of a smaller type and closer general arrangement. More than ever this work remains a mine of information which must be indispensable to all those who are concerned with industrial medicine. It has no serious rival in the English language, and it is to be hoped that successors to the author will be found to keep it abreast of the modern developments of the subject, and that further editions may be forthcoming from time to time as they may be required. Prosser White's *Occupational Diseases of the Skin* has become a

⁴ *The Dermatoses or Occupational Affections of the Skin*. By R. Prosser White, M.D., C.M. Fourth edition. London: H. K. Lewis and Co. Ltd. 1934. (Pp. xvi + 716; 72 figures on 66 plates. 35s. net.)

classic, and as such deserves immortality. The memoir of the author, by his friend Dr. W. E. Cooke of Wigan, which appeared in the *British Medical Journal* last January, has been expanded by Dr. Cooke as a preface to this posthumous edition.

AN ENGLISH LEECHBOOK.

The fifteenth century *Leechbook*,⁵ which has long been in the possession of the Medical Society of London, was brought to light when Mr. WARREN DAWSON catalogued the Society's library in 1932. It seemed to be interesting, so Mr. Dawson transcribed it, dedicated his transcription very appropriately to the honorary librarian, Dr. A. Francis Voelcker, and got it published by the Royal Society of Literature of the United Kingdom under the terms of the Dr. Richards Trust. The manuscript itself consists mainly of recipes for injuries, ailments, and affections of all kinds, arranged alphabetically. Its date is probably not later than 1443, and it does not differ greatly from the *Leechdoms* of an earlier period published by the Rev. T. O. Cockayne and by the Rev. George Henslow. The present manuscript is in English, and is easy to read by those who enjoy Chaucer, but Mr. Dawson has contributed a version in modern English for those who are less educated in their own language. He has, too, added explanatory notes, most of which are ingenious and correct, though others like "Pin and Web" and "Morpheew" are clearly wrong. In an appendix Mr. Dawson prints some medical prescriptions from a manuscript of the Tudor period used by various members of the Purefoy family.

Some of the recipes in the *Leechbook* are interesting, as, for instance, that "for the biting of a dog: Take cress and pennyroyal and seethe them in water and give him to drink. And lay of the dog's hair thereto if thou mayest have it." The prescription remains in common use at the present time as an injunction to "take a hair of the dog that bit you." The absence of any means of measuring short periods of time is exemplified in the recommendation to let the materials used in making a confection "seeth while thou may say this psalm miserere mei, deus." And again, when a longer time is required, "boil them in running water mile way," which is interpreted as whilst you walk a mile. Mr. Dawson has done a good work in publishing this manuscript, but it would have been still better if he had made an index, for, although it is arranged alphabetically, it is not easy to discover any individual recipe.

THE HISTORY OF MALARIA

The *History of Malaria in the Roman Campagna*,⁶ by the late Dr. ANGELO CELLI, who died at the age of 57 in 1914, while engaged in the preparation of the work, has been worthily completed by his widow, Madame ANNA CELLI-FRAENTZEL, who herself has made several interesting contributions to the subject. The book is divided into eight chapters, devoted respectively to the pre-Roman Period, the Roman Republic, the Empire, the early Middle Ages, later Middle Ages, Modern Period, Latest History, and Epilogue. In the pre-Roman Period and the early centuries of Roman history malaria was unknown, or if it did exist was so mild as to form no hindrance to civilization, traffic, and intensive cultivation. At the beginning of the period of Roman domination part of the Campagna

⁵ *A Leechbook or Collection of Medical Recipes of the Fifteenth Century*. By Warren R. Dawson, F.R.S.E., F.R.S.L., F.S.A.Scot. London: Macmillan and Co., Ltd. 1934. (Pp. 344. 25s. net.)

⁶ *The History of Malaria in the Roman Campagna*. By the late Angelo Celli. Edited and enlarged by Anna Celli-Fraentzel. London: John Bale, Sons and Danckson, Ltd. 1933. (Pp. viii + 226. 12s. 6d. net.)

at least was intensely inhabited and cultivated. The general decline, however, of the peasant class led to the spread of malaria. During the Empire malaria was widespread in Rome and the surrounding country, in spite of the improvement in the hygienic condition of the capital and its water arrangements, carried out by Augustus and his successors.

The introduction of Christianity into Rome was accompanied by an attenuation of the disease, but the barbarians who destroyed the aqueducts of the Campagna converted the land into a desolate and fever-stricken desert encampment, which caused heavy losses among them. In the later Middle Ages the popes and bishops made constant attempts to improve the condition of the Campagna by means of hydraulic works, but without success. The "air of Rome" proved particularly fatal to foreigners who were appointed to the papacy, as well as to the armies which invaded Roman territory. In the modern period, extending from the Renaissance down to the present time, the attempts were continued to reclaim the marsh land. At the end of the sixteenth century, however, and during the next two centuries, malaria became more extensive and violent, in spite of the revival of medical science and the introduction of cinchona bark in the second part of the seventeenth century. Although in 1870, when Italy became a united kingdom, a great effort was made to free Rome and the surrounding country from malaria, it was not until after Ronald Ross's discovery in 1898 that reclamation, colonization, and rational farming in the Roman Campagna began. During the first fourteen years of the present century Angelo Celli initiated a vigorous campaign against malaria, which led to the passing of special laws with regard to the sale of quinine, agrarian reclamation, and colonization. A copious bibliography is appended to the book.

THE SPAN OF LECTURES AND THE SPAN OF LIFE

There is no need to quarrel with the ambition to convey to the public an intelligent knowledge of the mechanism of the human body and of the methods by which the impairment of this mechanism by disease can be prevented. But success in these aims is not given to every author, and, in particular, it has not been given to Dr. FRANKLIN R. NUZUM in his book entitled *The Span of Life*.⁷ The directors of his hospital have urged Dr. Nuzum to the enterprise, and so far as literary exposition is concerned he has done well. It is his judgement in the choice of appropriate materials that we question. In his early chapters he deals with the heart and its diseases, and it is conceivable that on these topics something reasonable and helpful might be said to an attentive public. But what is the educational value of such statements as, "The blood makes a complete circuit of the body in twenty to thirty seconds"; "Five to six quarts of blood course through the body between three and four thousand times each day"; "During exercise the amount of blood pumped into the arterial circuit may rise to thirty-five pints per minute"; "Each red corpuscle makes the circuit from the left heart to the periphery of the body, thence to the right heart by way of the veins, to the lungs, and back to the left heart in twenty seconds"? Such propositions announced from the platform may well make a lay audience gasp and stare, but they will hardly provide either illumination for the mind or practical guidance in the conduct of life. Again, we should doubt the wisdom of an attempt to give to non-technical listeners an introduction to the significance of the electrocardio-

gram; or to describe to them the various theories of angina pectoris; or to engage their interest in the clinical and pathological features of coronary thrombosis. What actually happened at the Santa Barbara Cottage Hospital during these exercises we of course do not know, but we will venture a shrewd suspicion that not a few of Dr. Nuzum's listeners were successful in finding that effective protection from the pronouncements of the platform which secret and stolen slumbers conveniently provide. The popular lecture on medicine is a rare art, and it is not achieved in the volume before us.

Notes on Books

Laboratory Medicine,⁸ by Dr. DANIEL NICHOLSON, aims at supplying for medical students information on the indication, method, and interpretation of diagnostic tests which will prove most useful when they commence to practise. More highly technical diagnostic tests, which a physician would have performed for him by a trained pathologist, are outlined in principle and the interpretation given. As the author points out, no hard-and-fast line can be drawn between these two groups because physicians vary in their training and liking for laboratory work. But whether this book is made use of as a guide to the actual performance of these tests or only consulted for their interpretation, there is no doubt that it will be a very useful addition to the practitioner's bookshelves. The first edition was published three years ago. The work is now slightly larger, and contains descriptions of new procedures in clinical pathology.

The Pathology of the Urinary Tract, by Dr. PASTEUR VALLERY-RADOT,⁹ is one of a series of short books on different branches of medicine intended to serve as an introduction for the student coming fresh to the subject. It begins with a chapter on the symptoms for which patients suffering from urinary diseases first consult a doctor. Succeeding chapters describe methods of examination, and then discuss, in turn, the different diseases of the kidney and bladder. A book of this sort would be very useful to students in this country, and if any teacher is considering the question of ministering to this need he would probably gain a good deal from a study of the volume which Dr. Vallery-Radot has completed.

The January issue of *Arquivos de Medicina Legal e Identificação*,¹⁰ the official publication of the police of the Federal district of Brazil, edited by LEONÍDIO RIBEIRO, director of the Brazilian Institute of Identification, is an imposing-looking volume. It contains a large number of original articles, clinical lectures, reports of cases of forensic interest, together with reviews and abstracts. The original articles include: psychological essays on pain, by E. Mira; the cardio-pneumo-psychogram in the detection of lying, by I. Castellanos; the comparative method in psychopathology, by A. Ramos; the fingers in the elucidation of crime, by F. Belletti; and hysteria and errors of diagnosis, by Nerio Rojas. The chief subjects of the lectures are as follows: asphyxia in general, by A. Costa; psycho-analysis, by H. Roxo; anthropology, by J. Bastos d'Ávila; identification by the teeth, by Aloysio de Carvalho Filho; the legal protection of the child by Levi Carneiro; and investigations of paternity, by the editor, who also delivered lectures on the criminal code of Brazil and the role of the medical criminalist. The volume is sent free to foreign scientific institutes and specialists in forensic medicine on application to the editor, Dr. Leonídio Ribeiro, Instituto de Identificação, 84, rua do Lavradio, Rio de Janeiro.

⁷ *Laboratory Medicine: A Guide for Students and Practitioners*. By Daniel Nicholson, M.D. Second edition, thoroughly revised. London: H. Kimpton. 1934. (Pp. 566; 124 figures, 3 coloured plates. 30s. net.)

⁸ *Pathologie de l'Appareil Urinaire (Reins, Vessie)*. Par Pasteur Vallery-Radot. Paris: Masson et Cie. 1933. (Pp. 202; 10 figures. 22 fr.)

¹⁰ *Arquivos de Medicina Legal e Identificação*. Edited by Leonídio Ribeiro. Rio de Janeiro: Imprensa Nacional, 1934. (Pp. 403.)

⁷ *The Span of Life: As Influenced by the Heart, the Kidneys, and the Blood Vessels*. By F. R. Nuzum, B.Sc., M.D. London: Baillière, Tindall and Cox. 1933. (Pp. xii + 108, 9s.)

Dr. KATE CAMPBELL HURD-MEAD's little work on *Medical Women of America*¹¹ is, as its subtitle states, a short history of the pioneer medical women of America and of a few of their colleagues in England. The leading medical women were Elizabeth Blackwell and her sister Emily, who left England and qualified in 1849 and 1852 at New York and Cleveland respectively, and subsequently played an important part in the medical education of women; Mary Putnam Jacobi, who gained a high reputation as a practitioner, lecturer, and writer, and was the first woman admitted to the New York Academy of Medicine; Ann Preston, who helped to found the Women's Medical College of Philadelphia in 1850, where she became professor of physiology and then dean; Marie Zakrzewska, founder of a hospital for women and children at Boston in 1862; and Eliza Mosher, professor of hygiene and dean of the Women's University of Michigan. The English women graduates mentioned are Sophia Jex-Blake and Elizabeth Garrett Anderson, the founders of the London School of Medicine for Women, and Dame Mary Scharlieb, and many eminent living specialists in obstetrics, gynaecology, and other departments of medicine. The appendix contains the autobiography of Elizabeth Cushier, the leading woman surgeon of her time, who graduated in 1872 and died in 1932 at the age of 93, and is followed by portraits of the principal persons mentioned in the text, including the author.

High Days and Bye Days,¹² by RALPH GREAVES, is medical only in that it will appeal to those members of the profession who love hunting and survive the atmospheric change from that of hay to that of petrol, which has taken place in this country during the life of James Cockayne (1860-1929), who was connected with packs not only in England but in Hungary. It is a brightly written story based on his diaries, but, as the author confesses, somewhat apocryphal rather than gospel in parts. The printing and general get-up of the volume are an appropriate garb for its attractive contents.

¹¹ *Medical Women of America*. By Kate Campbell Hurd-Mead, M.D. New York: Froben Press, 1933. (Pp. 95. 1 dollar.)

¹² *High Days and Bye Days, being Stray Chapters from the Life of a Huntsman*. By Ralph Greaves. London: Philip Allan, 1933. (Pp. xii + 244; illustrated. 12s. 6d. net.)

Preparations and Appliances

ELECTRO-MEDICAL APPARATUS FOR ALTERNATING CURRENT MAINS

With the replacement all over the country of direct by alternating current from the national grid, suppliers of apparatus for electro-medical treatment are adjusting their models accordingly. The Medical Supply Association, Limited (167-173, Gray's Inn Road, W.C.1) sends us a catalogue of 1934 models, which is wholly concerned with new apparatus for alternating current mains. Particulars are given of several types of rectifiers for the production of galvanic and sinusoidal current for ionization, electrolysis, muscle reaction testing, and similar purposes. Another range is concerned with radiant heat and infra-red applications. One apparatus consists of a telescopic stand, with extension arm and aluminium reflector, for taking infra-red and radiant heat elements over a treatment couch or bed. A portable diathermy apparatus is a new introduction, connecting to any alternating current supply from 70 to 250 volts, and built into a compact attaché case, weighing altogether only twenty-three pounds. With it are supplied eight electrodes of various sizes, suitable for treatment of different parts of the body. A number of devices are included for what is known as short and ultra-short electric wave therapy. By short-wave therapy is meant treatment in the electrical condenser field with high-frequency energy of from ten to thirty metres wave-length, while ultra-short-wave therapy corresponds to wave-lengths of below ten metres. With these waves a uniform distribution of energy is secured over the part of the body between the electrodes, and consequently, if the electrodes are suitable, it is possible to obtain localized effects at depth. The apparatus is for connexion to alternating current supplies of forty to sixty cycles.

SOME SURGICAL DIFFICULTIES IN INDIA

BY

RUFUS C. THOMAS, F.R.C.S.Ed.

CHIEF MEDICAL OFFICER TO HIS LATE HIGHNESS THE MAHARAJAH
JANSAHEB OF NAWANAGAR

So far as I am aware very little has been written by surgeons in India in regard to the difficult conditions encountered by them in the course of their work. My own experience has, no doubt, been that of hundreds of other surgeons, particularly those in the I.M.S.; but I am not aware that these experiences have ever been put on record, and I feel that a short description of some of the conditions might be of interest, both to those who have encountered the same difficulties, and to others to whom surgery abroad has so far been only a name. Six years' surgical work in an Indian State, ruled over by one of the most enlightened of Princes—the late Ranji, of world-wide cricket fame, whose people may be taken as typical of India in general—seems to me to justify this excursion into print. As far as the people themselves were concerned the most obvious thing noticed was their innate distrust of surgery and all its works, coupled with a blind ignorance and lack of ability to understand the most simply expressed reasons for recommending any operation to them. Even the so-called better classes took a lot of convincing that whatever was recommended was solely for their own good.

THE HOSPITAL: OLD STYLE

When I arrived I found the hospital was a sort of combination of "ancient and modern." It was equipped with the telephone and electric light, but there was no provision for hot and cold water, baths, sanitation, or storerooms for such things as sheets, blankets, and all the hundred-and-one articles required for the proper running of a hospital on modern lines. The building itself was a good one, but an operating theatre had been left out of the builder's calculations, and one of the main wards had been taken over to remedy the omission. The bed accommodation was reduced thereby considerably. Sheets, blankets, and other hospital stores were kept in wooden cupboards dotted all over the place, chiefly on the verandas. There were two privies attached to the hospital itself, and a row of foul places at the back of the compound, which were supposed to be cleaned out periodically by the Bhangis (sweepers). This necessary duty was always forgotten unless one led the Bhangis literally by the nose to their task. When the wind blew from the north-east the hospital got a practical illustration of what the expression "Odours of Araby" can mean.

There being at first no such thing as a bathroom the patients were put straight into bed as they arrived. As many of them had walked miles from outside villages there was no possibility of keeping sheets clean. Beds and mattresses were, of course, bug-infested. The water supply for all purposes was obtained from a well in the compound, where a pair of bullocks plodded their weary way, hour after hour, up and down a track, pulling a skinful of water at each journey. Water for washing patients or floors, water for cooking or cleaning food utensils, for the surgeon's hands, and for the operating theatre—all of it came up in the skin. The water for the operating theatre used to be boiled in buckets in the cook-house by the Brahmin cook, and then carried across the compound to the theatre by the ward boys. *Labor omnia vincit*. But I always wondered how sterile, if at all, was the water I used for the first six months. It was a decided shock after the modern sterilizing methods of British hospitals. Later on I was able to alter all this.

The operating theatre was, as I have said, one of the large wards appropriated for the purpose. In this room everything necessary was done. It constituted surgeon's changing room, preparation room, anaesthetizing room, and operating theatre all rolled into one. On an operating morning there would be about nine primus stoves roaring away, some with instruments being sterilized, some with towels, others with dressings. The doors and windows were of necessity kept closed to keep out the dust of

the compound and incidentally the relatives of the poor unfortunate patient. It was possible to keep the dust out. We were sometimes not so successful with the relatives, and I have had to suspend "operating" while the theatre was being cleared of a horde of anxious "friends," who had succeeded in storming the door. On one or two occasions they forbade the operation after I had started it, and would have removed the patient there and then if allowed. A fearful and timid people. The heat of the theatre, aided by the sun and the primus stoves and the number of people in it, rose steadily till at last it must often have reached 110° F., almost double the temperature of the English theatre. I lost gallons of fluid in sweat. Six months after I arrived I transferred the operative work to two small wards, installed electric sterilizers and other refinements, and my theatre life became much more bearable. Even here, however, the problem of cooling the theatre was a formidable one. During the hot weather my plan was to have a block of ice weighing a maund (40 lb.) placed in a large bowl, behind which a hand-fan blew its full blast towards us. This certainly made a considerable difference. Unfortunately, however, it cooled one side of us more than the other. I took the temperature on the operating table after one morning's work and found it to be 107° F.

THE PATIENTS

The condition of many of the patients on admission to hospital was appalling. The ovarian cyst reaching to the ensiform cartilage is in England, happily, a rarity. In India it is a common occurrence, and the difficulties of removal can be imagined. It was a common thing to evacuate pus in half-gallons from a liver abscess or an appendicular abscess, the duration of whose history had been a month or more, while carcinomas of the breast often presented themselves with a huge fungating and stinking mass, the contemplation of which almost brought on an attack of vomiting. The only course open to the surgeon was to remove the breast to get rid of the foul and penetrating smell; all hope of complete eradication of the disease had, of course, passed months before. How these poor women could have borne their own conditions for so long was a mystery to me. I saw a chronic mastoid which had burst of its own accord, the opening now full of maggots. Maggots in the nose was quite a common condition. It was treated with plugs of gauze soaked in pure turpentine. Chronic suppurating ulcers of the leg were, on being radiographed, found to be the result of an osteomyelitis affecting the whole length of a tibia or fibula, or both. Tuberculous disease of the spine was quite common also, and was often accompanied by abscess formation, the bursting of which was the reason for seeking medical advice. Here one's suggestion of a plaster jacket was refused on the ground that the time was too long to secure the parents' permission for treatment. Even early cases, those merely with deformity and pain but no abscess, were often taken away on hearing that a plaster would have to be worn for months to ensure a cure.

SOME CASES

A few examples will serve to show some of the difficulties one had to contend with. Ignorance had a tremendous influence, as can be imagined.

I well remember a girl of about 10 years of age being brought in with a sarcoma of the lower end of the femur. At that time I had no x-ray plant, but it was not needed, for the diagnosis was obvious. I explained to the parents that amputation was the only course open, to save the child's life. They refused at once. On being asked their reason for depriving their child of its chance of life they said that nobody would be prepared to marry her if she only had one leg. I then pointed out that if the leg was not removed she would be dead in a year or less. The answer came immediately: "We can bury her, but who will marry her with one leg?" I spent another half-hour trying to persuade them to see reason, and even went to the length of getting a priest to talk to them, but to no avail.

Another very similar case occurred a year or so later, when the mother of a girl of about the same age, with a sarcoma above the wrist-joint, on hearing that an operation was necessary, took her child away at once.

Until I got together an efficient nursing staff it used to be quite a common occurrence for patients to disappear mysteriously in the night. The night before an operation was a favourite time, but it used to happen even several days after an operation, too. Parents who had given their consent a day or so before would get more and more "windy" as the ordeal approached, till at last their fears would get the better of them and they would remove their child, bag and baggage, while the back of the dresser on duty was turned for a moment. Even an abdominal incision with stitches still *in situ* did not deter them from these nocturnal flights. Sometimes they came back, sometimes not.

One of these disappearing patients, I remember, was an old man from a village miles out in the district, who had come in with an enlarged prostate. He had been catheterized on many occasions, and had at last been persuaded to try the hospital. I did a suprapubic drainage first, with which he was delighted, as of course it relieved his difficulty of micturition at once. Ten days later the necessity for the removal of his prostate was explained to him, and he agreed without demur. The morning of his operation, however, he was missing. Four months later he turned up again, with his tube in his hand and his suprapubic wound closed. His bladder difficulty had returned, much to his astonishment and annoyance, hence his return to the fold. This time he submitted to Fate without a murmur, and I removed his prostate a fortnight later. I found out, incidentally, that he had blossomed out into quite a hero in his village, as he used to take his suprapubic tube out to show his friends how his urine came out from his stomach, putting the tube back after each demonstration. He must have suffered considerable agony of mind as well as great loss of prestige when his fistula closed!

The fear of an operation loomed very large in the minds of these simple and timid people. They sometimes refused in face of the certainty that their condition was bound to be fatal if nothing was done. Many a weary hour have I spent trying to convince a patient that an operation would give him a good chance of being cured, and that to do nothing was as good as signing a death warrant. There was, of course, a religious influence at work in those cases where patients were taken out of hospital against advice when they were very ill. Certain ceremonies had to be performed in their own house for a dying man. The fact that the patient still had a chance of recovery if left in the care of the hospital staff did not weigh much if the relatives once got the idea that he might die. The removal to his own home sometimes entailed a journey across country in a bullock-cart, of ten, perhaps fifteen, miles. To a man with, perhaps, a suppurating hydatid of the liver just drained, or a pneumonia approaching the crisis, the result of such a journey was a foregone conclusion.

Another case comes to mind of a woman whom I had taken in from a village, in difficult labour. I had obtained the husband's permission to do a Caesarean section, had actually removed the child, and was proceeding to suture the uterus when the husband burst into the theatre and demanded to take his wife home immediately. When it was explained that the operation was almost over he waited outside, and when I came out repeated his intention of removing her forthwith. The danger of such a course did not seem to impress him, though it was fully explained to him in his own language by my house-surgeon. After much argument he eventually agreed to leave her in the hospital for a week. He made several nocturnal attempts to remove her before the week was up, and we finally had to let her go. I sent someone to her house to remove the stitches, and—*mirabile dictu*—she recovered.

Another habit of some patients was to take their dressings off at night and have a look at their incisions. If there was a tube *in situ* they would often remove this too. One old man made a habit of removing the tube from his suprapubic every night and replacing it in the morning, until he was caught in the act by the house-surgeon.

THE PROBLEM OF CASTE

Religious customs often made for great difficulties in treating patients in hospital. There is a caste of Hindu called the "Bhatia," the members of which are precluded

from eating any food not prepared by their own hands. Even a husband's hands are apparently taboo. One such lady came to me, with, I think, an ovarian cyst. The question of an operation was put to her, whereupon she said she could only remain in hospital for three days, owing to this food question. The difficulty was such a real one, and she was so insistent on it, that I had to compromise by agreeing that she should go home on the fourth day, which she did. Other Bhatias came in occasionally, and all had to be accommodated in the same way.

The problem of the "Untouchable," those unfortunates who, spurned and despised by their own people, did all the dirty work for the whole of India, getting in return a minimum of pay and a maximum of abuse, was one which gave much trouble at first. They were never admitted into the main hospital, but had two small wards separated from the main building. No caste Hindu would remain in a ward which contained an Untouchable, no matter how ill either or both might be. The shadow of an Untouchable falling on the food of a Brahmin was enough to contaminate that food, and the meal was at once discarded. Later on, when the numbers of in-patients began to rise and beds were continually full, the outside wards had to be used for septic cases, and the question arose as to where to put the Untouchables. I decided to make a fight against the prejudice towards them, and admitted the next one into the main hospital, among the other patients. There was an immediate protest from several of the other patients, who, of course, were caste Hindus. They threatened to leave the hospital if the poor outcast was not removed from their presence. The Untouchable was, as far as I can remember, suffering from some acute abdominal condition, which required immediate operation, but although this was explained to the objectors, and an appeal made to them on these grounds, it had no effect. I then appealed to their religious feelings, but this, to my disappointment, also had no effect, and I was practically given an ultimatum to the effect that either the Untouchable was to go or they would. This I countered by refusing to move the Untouchable. Indeed, I had no available bed for him, except by putting him out on the veranda, where he would have stood every chance of getting pneumonia, as it was the cold season and the weather was very bitter. There were many mutterings and black looks for the rest of that day, but the objectors gave in ultimately, only making the request that they should all be placed at the other end of the ward, as far from the outcast as possible.

This attitude towards the outcast community was, incidentally, very inconsistent, as many of my staff—my house-surgeon, house-physician, anaesthetist, and so on—were all very high caste Brahmins themselves, did all they could for the outcast as well as for the Brahmin, and backed me up most loyally in this fight against a religious prejudice which did not even consider human lives in the scale of justice.

I had the same sort of trouble with the dressers in connexion with such essential nursing matters as the giving of bed-pans to bed-ridden patients. They refused in a body to carry out these duties, and threatened to resign immediately unless such tasks were relegated to the Bhangis (Untouchables). I had always tried to ensure that the Bhangis did not enter the wards, not on account of their "untouchability," but because their work was such that they were better outside the ward than in, from the point of view of asepsis and general cleanliness. I won this battle—a most important one for me, as will be readily admitted—by turning the tables, so to speak, on the dressers. I asked their spokesman, a very astute and hard-working boy, what arrangements he would expect me to make for him, if he was ever admitted as a patient, in view of the fact that he, a Brahmin, could not, by his religious laws, allow a Bhangi to give him a bed-pan. He was very quick to see that he had put himself in an untenable position, and was in danger of being hoist on his own petard. He at once took his fellows aside, and convinced them that I was right.

THE "QUACKS"

Before terminating this somewhat depressing article I would like to mention the dangers to which the people often exposed themselves by consulting a class of "quacks" who styled themselves "Mulls," the equivalent of bonesetters—men who were really wrestlers. These people claimed to be masseurs and manipulators, and would "treat" any kind of deformity which was brought to them by forcible movement and the application of splints and what-not. There are, in the museum at Jamnagar, three forearms, removed for gangrene, the result of the "treatment" of fractured radius and ulna by some of these menaces to health. Splints had been applied by them, made of bamboo or the like, and left on for two or three weeks. When taken off a blackened and ghastly mess was revealed, and the victim was then brought to hospital. These "Mulls" used to treat the deformity of a tuberculous spine by placing the knee over the angle of deformity and forcibly trying to extend the trunk. Other unqualified "practitioners" were equally dangerous, treating cancer of the breast with nitric acid, caustic ointments, and such-like "remedies." Many of them had notices on their doors, positively "guaranteeing" the cure of tuberculosis, asthma, chest diseases, and so on.

CONCLUSION

The above are some instances of what may be encountered in surgical practice in India. It is not a pretty tale. Some may accuse me of "poetic exaggeration." This is a true story—much stranger than fiction. I shudder to think what the early surgeons must have gone through when there was no electric light, no fans, none of the modern ameliorations of conditions of work. The sufferings of the people of India must have been simply beyond the realm of imagination. The brighter side of the picture came during the last three years of my service, when I had the pleasure of superintending the building of a new hospital of 100 beds, and in which task I had the never-failing encouragement of His late Highness, the Maharajah Jamsaheb. This building, which with its equipment cost about six lakhs of rupees (£45,000), was, as nearly as I could make it, designed and fitted out according to British standards, had its own sanitary system, hot and cold water, baths, electric sterilizing unit (which was a great boon), two theatres, and every modern convenience. It was a red-letter day when we moved into it. The joy of working in a modern environment is best appreciated by those who have spent some years in the other manner.

Conditions, then, became perfect in 1932; but the ovarian cyst filling the abdominal cavity, the carcinoma of the breast a foul sloughing ulcer, the liver abscess as big as your head—all these remain. The education of the people up to modern methods of medicine and surgery will still take much time. It has been said that only one-tenth of the Indian people are within reach of hospital treatment. Mortality in childbirth, infant mortality, the death roll from epidemics, fevers, and so on—all these still reach colossal figures. A gigantic task lies in front of those who serve India's gigantic population. It needs endless perseverance on the part of the workers, an unceasing devotion to duty of a not too well paid body of medical practitioners, and, lastly, and equally important, the financial and moral support of those in authority.

The annual meeting of the American Orthopaedic Association will be held at Rochester, Minnesota, from June 6th to 9th, under the presidency of Dr. Melvin S. Henderson. The main subject in a full programme of papers, discussions, and demonstrations is the open treatment of congenital dislocation of the hip. Mr. Rowley Bristow, orthopaedic surgeon to St. Thomas's Hospital, will be the guest of the association, and will read a paper on internal derangements of the knee. The honorary secretary is Dr. Ralph K. Ghormley of the Mayo Clinic, where the scientific sessions will be held.

PATHOLOGY OF INTESTINAL OBSTRUCTION

In a paper read before the Medical Society of New York, Atchley¹ emphasizes the essential similarity between the secondary effects of high intestinal obstruction and those of such diverse conditions as cholera, Addison's disease, extensive burns, and diabetic acidosis. The serious complications of all these diseases he attributes not so much to the primary aetiological agents themselves as to the physiological responses of the tissues to these agents, consisting in every case of a loss of water and salts, and leading to a common state of dehydration, diminished blood volume, shock, and peripheral circulatory failure. He finds support for his views in the unique effects of sodium chloride solution in intestinal obstruction and cholera, and in the recent discovery by Loeb that many of the symptoms of Addison's disease are due to a loss of sodium. Further confirmation is found in the experimental work of Gamble, who showed by analysis that in the case of high obstruction all the chemical changes in the body fluids could be fully explained by the loss of gastro-intestinal secretions, particularly sodium chloride, either by vomiting or passive accumulation in the intestine. Raised blood urea and renal failure are the direct results of diminished blood volume and capillary stasis, and it is unnecessary to postulate any toxic action on the kidneys. In low obstruction and obstruction with gangrene other factors—bacterial action, interference with blood supply, and tissue necrosis—complicate the issue, but the factor of dehydration here also plays an important part. Atchley makes no attempt to explain the precise mechanism by which dehydration is brought about in these diseases, but he presents a simple and coherent view of the problem which, so far as it goes, is consistent with the known facts.

The arguments of Sweet² are less easy to follow. Seeing a close resemblance between high obstruction and the condition produced by bilateral adrenalectomy in dogs, he argues that the secondary effects of obstruction are the result of adrenal damage, the latter being caused by the action of a toxin. To him the external loss of water and salts is of subsidiary importance; the essential pathology is a disturbance of the water exchange between the blood stream and the tissues. He quotes the experiments of Swingle, who showed that one of the functions of the adrenal cortex is the maintenance of a normal volume of circulating fluid; cortical damage results in a withdrawal of fluid from the blood stream by capillary transudation, which pro-

duces the pathological basis of shock. Sweet explains the preservation of consciousness in these states by assuming that the tissues (including the brain cells) "hold" their normal quota of fluid against a depleted blood stream; and the loss of consciousness in severe haemorrhage by supposing that the circulation here makes good its losses at the expense of the tissues, because the adrenals remain intact. There are undoubtedly points of resemblance between the clinical syndrome of acute intestinal obstruction and the condition produced by bilateral adrenalectomy in dogs, but, as Standard points out in the discussion, it is dangerous to assume a common aetiological factor because of a clinical similarity. Sweet's theory is defective in assuming, not merely the presence of a toxin, but its peculiar mode of action on the adrenal gland. The latter assumption has hardly received serious consideration, though Sweet states that he has found necrosis of the gland following intestinal obstruction. The question of toxins has been the subject of numerous experiments, and it is probably true to state that no convincing evidence has yet been produced for the existence of a specific toxin in obstructed intestine free from gangrene. Toxic substances have certainly been found, but the investigations of Wangensteen and others, quoted by Best, Newton, and Meidinger,³ would indicate that the contents of the normal and obstructed bowel are equally toxic. In view of the possibility of an increased rate or selectivity of absorption of normally present toxins under the conditions of obstruction, these workers have carried out a further series of experiments on the absorption of colloid and crystalloid dyes from the intestinal lumen above and below the site of obstruction. They found no evidence of such an increase in the case of the crystalloid dyes, nor of any absorption whatever of the colloid dyes. They suggest that the lethal effect may be determined by a physico-chemical disturbance rather than by toxic action, due to a failure of the upper intestinal contents to mix with the lower.

The therapeutic requirements of this type of intestinal obstruction are fortunately more clearly defined than are our theories of its pathology. By far the most important of the non-operative measures is the restoration of the water and salts which have been lost to the circulation. The principle of replacement therapy is well established and needs no advocacy; it conforms with theoretical requirements, and has stood the tests of clinical experience and laboratory experiment. This aspect of the subject has been dealt with by numerous writers, and was discussed at the British Medical Association Meeting in 1932.⁴ There is no standardized technique, but normal saline given by the intravenous route meets immediate needs, and is probably the method in most common use. The increase in blood volume so produced may be maintained by slow, continuous infusion, hypodermic or intravenous. Injection of hypertonic saline rapidly compensates for loss of sodium chloride; increases the osmotic pressure of

the blood, so tending to prevent further loss of fluid ; and notably stimulates peristalsis. For the latter reason its use is limited to the period immediately preceding operation, or after the obstruction has been relieved. The addition of 5 per cent. glucose, preferably with insulin, provides a ready source of energy when it is greatly needed. The relief of distension, especially before inhalation anaesthesia, is also of importance ; this can best be accomplished by the duodenal tube. Other accessory methods of treatment are the use of *B. welchii* serum and bile enemata. In simple high obstruction toxæmia is not a prominent feature. No benefit, therefore, can be expected from the use of serum, and this appears to be borne out by experience. It is worthy of note, however, that pathological changes have been found in the adrenal gland following death from *B. welchii* infection, a fact which may possess some significance in view of Sweet's theory of adrenal failure in obstruction. In this connexion, too, the recent introduction by Swingle and Pfiffner of an active extract of the adrenal cortex offers the possibility of an entirely new factor in treatment which is worthy of investigation.

DEFECTIVE DIETS

While the experimental evidence regarding the effects of a deficiency of vitamins is clear in animals in which the deficiency is isolated, the problem is complicated in man by the fact that a vitamin deficiency in his diet is rarely if ever complete, and is generally associated with a partial shortage of other important substances. The need for the clinical testing of the value of vitamin supplements by controlled experiments is therefore obvious. In our present issue Dr. Robert Sutherland describes his investigations into the effects of the addition of supplements of vitamins A and D to the diet of children of the poorest classes. The effects for which he specially looked were those upon growth, general nutrition, susceptibility to infection, and resistance to established disease.

For a period of six months a concentrate of vitamins A and D was given to 294 children attending the North School, Peterhead. It was shown by a census of the parents' occupations that these children were drawn almost entirely from the poor working classes. They had 281 contemporaries as controls. Each child in the treated group received a vitamin supplement equal in vitamin A to more than one ounce of cod-liver oil daily. The daily dose of vitamin D was 2,400 international units. The results of the administration of vitamin supplements were found to be disappointing. This was all the more surprising since a dietary survey clearly indicated that the diets were deficient in many respects. The rate of growth of the treated children was only slightly better than that of the controls, while susceptibility to infection and resistance to established disease were apparently unaffected by the treatment. Dr. Sutherland believes that the cause of the failure lay in the fact that the vitamin supplements made good only one dietary shortage, and left uncorrected asso-

ciated deficiencies of equally essential constituents of the diet. The correction of one partial deficiency in man while these other associated deficiencies remain uncorrected can never produce the dramatic results that are obtained from the restoration to the otherwise complete diet of experimental animals of a factor which previously was entirely absent. Support of this contention was obtained from a comparison with an earlier nutritional experiment carried out in the same school in 1927 and 1928, when a daily milk ration was given as a supplement. In the milk experiment of 1928 increases of 24 per cent. in height and 45 per cent. in weight occurred, as compared with 8 per cent. and 7 per cent. respectively in the present experiment. In searching for an explanation of these results, Dr. Sutherland suggests that the milk supplements succeeded where the vitamin addenda largely failed, because, besides correcting the vitamin deficiency, they made good the associated deficiencies which almost always accompany a shortage of vitamins. In this respect milk has particularly beneficial effects compared with vitamin concentrates, because of its rich supply of first-class protein and minerals.

The attention of the medical profession has been focused so strongly on the problem of vitamin deficiency, and the results of animal experiments have been so impressive, that the importance of correcting the multiple deficiencies which almost always go hand in hand with a vitamin deficiency is apt to be overlooked. Where there is a clear indication of a specific vitamin deficiency as occurs in rickets or scurvy, administration of a concentrated preparation of the requisite vitamin is good therapeutic practice. But in the absence of gross signs of vitamin deficiency the indiscriminate administration of vitamin concentrates is evidently of doubtful value. The cheapest and best way of preventing nutritional disorders, and of increasing resistance to disease in so far as that can be done by nutritional measures, is to improve the diet as a whole. Provided the diet contains adequate amounts of milk, eggs, and green vegetables, the occurrence of a deficiency of vitamins, minerals, or protein is unlikely.

SAFE MILK

We have consistently advocated in these columns that until milk has been made safe at the source pasteurization is the best way of protecting the population from bovine tuberculosis and other infections that are conveyed by milk, such as scarlet fever, septic sore throat, and undulant fever. The matter has recently been considered by the Royal College of Physicians, and in a letter to the *Times* of May 1st Lord Dawson communicated the following resolutions passed at the comitia held on April 26th: "(1) That a daily ration of milk is important for the growth and health of children. (2) That the risk of tuberculosis and other diseases following the consumption of raw milk is considerable. (3) That such risk can be obviated by the use of milk submitted to low-temperature pasteurization, as defined in the official Order. (4) That such pasteurization does not materially interfere with the

nutritive value of the milk." The College, while realizing the importance of milk being produced from cows free from infection and under conditions of cleanliness, recommends: "(a) That local sanitary authorities should be given power to require that milk sold within their areas should be pasteurized under official control. (b) That steps should be taken to permit of the pasteurization and sale, as such, of milk from tuberculin-tested herds. (c) That in areas where adequate pasteurization is at the moment impracticable milk should be boiled before use." Lord Dawson's statement that "within the medical profession there is for pasteurization a consensus of opinion the strength of which is perhaps unfamiliar to those occupied in the world of politics" was confirmed, if confirmation is needed, at a special meeting of the Joint Tuberculosis Council on April 20th, when a memorandum on this question, prepared by Professor G. S. Wilson, was considered and discussed. It was felt that in the prevention of tuberculosis of bovine origin we are behind other countries, notably the United States of America and Canada. A resolution was passed welcoming the prospect of an increased milk consumption, but averring that the Government proposal to subsidize a milk ration for school children should be supported only if the safety of the milk supplied was ensured by adequate pasteurization or boiling.

VITAMIN A DEFICIENCY

An important investigation into the results of vitamin A deficiency in children has been conducted by Dr. Helen Mackay at the Queen's Hospital for Children, London, working as a member of the scientific staff of the Medical Research Council. In the current number of the *Archives of Disease in Childhood*¹, which is incidentally the fiftieth issue of the periodical, this author gives a most valuable survey of present knowledge of the clinical effects of deficiency of this vitamin, with special reference to children. The results of her own investigations are to be reported in the next number. It is true that severe vitamin A deficiency rarely, if ever, occurs alone, but from the literature and her own studies, Dr. Mackay has produced a valuable clinical picture of the likely course of such a defect. The child, otherwise in apparently good health, will develop an increased susceptibility to infections of the skin; he may have boils, sores, impetigo, napkin rash, or other evidence of skin sepsis, and this susceptibility continues throughout the disease, the lesions often being chronic. Later the skin may become drier and show desquamation. There may be periods of looseness of the bowels, followed in some instances by a chronic diarrhoea and retardation of growth. The child will probably become lethargic and lose the alertness of health. The hair will lose its normal gloss, and if the child belongs to a dark-skinned or yellow race some slaty pigmentation of the conjunctiva and skin will probably appear. The voice frequently becomes hoarse, and bronchitis may develop. The abdomen tends to be enlarged at this stage, and there is a great eagerness for food. Evidence of night-blindness—the classical symptom of vitamin A deficiency—now begins to develop, most easily shown if the child is old enough to play in the dusk. Objective eye changes are found later, and may consist either

of some conjunctivitis or a mild degree of xerosis with the "foam spots" described by Bitôt. If the deficiency still remains untreated the weight will become stationary and even begin to fall. An irregular pyrexia may occur, possibly from diminished sweating. The skin becomes shrivelled, hair falls out, and the eye changes progress with involvement of the cornea. Death most often occurs from diarrhoea or from pneumonia. The older the child the slower the course of the disease. This is briefly the clinical picture, although the order of onset of the symptoms and the dominant changes vary from case to case. The incidence of vitamin A deficiency in Europe is probably less now than it used to be, but Dr. Mackay suggests that the evidence she is bringing forward in Part 2 of the study supports the view that deficiency of a slight grade is not uncommon among the infants of the poorest sections of the population in this country. Eye changes, as the clinical summary suggests, are clearly not the earliest symptoms, and it is with reference to infections of the skin that her work is most suggestive. No quantitative knowledge exists as to the vitamin A requirements of children, and it is suggested that in some circumstances even a breast-milk diet may provide insufficient vitamin A for a baby. If treatment is begun early the prognosis at all ages is good, but if this is delayed then there is a serious risk of loss of vision. Dr. Mackay's object in producing this clinical summary is to enable clinicians to recognize the disease at an early stage. She is also anxious that pathologists should keep in mind the characteristic epithelial changes. We would take this opportunity of congratulating Dr. Mackay upon the distinction of being the first woman to become a Fellow of the Royal College of Physicians of London.

BRITISH EMPIRE CANCER CAMPAIGN

A meeting, at which H.R.H. The Duke of York was present, was held at the Mansion House on May 1st in aid of the Empire Day appeal of the British Empire Cancer Campaign. The Lord Mayor presided over a distinguished company, including the Minister of Health, Lord Moynihan, Lord Horder, Sir William Willcox, Sir Francis Fremantle, Sir Cuthbert Wallace, many other members of the Grand Council and the various committees, and a number of mayors of metropolitan boroughs. The Duke of York reminded the company that at the Mansion House ten years ago he had said that some day the mystery of cancer would be lifted. It could not be claimed that that had fully happened, but the shadow gave signs of slowly passing. The progress of research during the ten years had been wonderful, though much remained to be done. It had not been the policy of the Campaign to husband its financial resources, but it had applied them liberally in the way of grants, and it had fulfilled every reasonable claim made upon it to aid research. The result was that its finances had been heavily depleted, and an Empire Day appeal was being organized, towards which the King had already contributed £100, the Queen £50, and other members of the Royal Family had made donations. The co-operation had also been promised of a thousand mayors and heads of local authorities. Lord Horder spoke briefly in thanking His Royal Highness and in expressing gratification at the presence of the Minister

¹ April, 1934, ix, 65.

of Health, whose Department evidently realized the importance of this greatest of all problems in medicine to-day—a problem which he was sure would yield to careful observation and patient research. Sir Hilton Young said that the number of recorded deaths due to cancer continued to increase. It was now second in the list of fatal diseases. The task of the Campaign was mainly to promote and co-ordinate research concerned with causation, to a lesser extent with diagnosis by laboratory methods, and with treatment. He was confident that local government authorities would help cordially in the creation of a public opinion in support of the present efforts of the Campaign. Mr. R. C. Davis, vice-chairman of the Executive Committee, mentioned that up to this year the Campaign had made grants totalling just over £175,000, largely to the great hospitals and research centres, but grants to the total of £26,400 had been made to individual workers in London and five other cities. Professor W. S. Lazarus-Barlow, vice-chairman of the Investigation Committee and chairman of the Appeal Committee, said that during the thirty years in which he had been connected with cancer research the type of investigation had been modified. At the same time, it must not be thought that the paths pursued thirty years ago had proved fruitless. The surgeons of that day had accepted three years' freedom as a criterion, and now looked forward to ten years of freedom from the disease. Although this extension from three to ten years indicated greater respect for the enemy, it showed also a sense of growing mastery over the enemy. The work on radium and x rays told the same story. He claimed that by virtue of the financial help the Campaign gave to institutions and researchers, and by its associations and affiliations throughout the British Empire and its friendly relations with cancer research organizations in foreign countries, it was a live body worthy of national and imperial support. Mr. Lockhart-Mummery proposed, and Mr. Cecil Rowntree seconded, a vote of thanks to the Lord Mayor for the hospitality of the Mansion House.

A NEW ANTISPASMODIC

The opium alkaloid papaverine has a powerful depressant action on plain muscle, and on this account finds a certain amount of employment in therapeutics. A new synthetic derivative of papaverine named perparine has recently been investigated¹ which has a more powerful action in this respect. Papaverine consists of an isoquinoline nucleus united with a benzene nucleus, with two methoxy groups attached to each nucleus. Perparine has the same structure, except that the four methoxy (CH_3O) groups are replaced by four ethoxy ($\text{C}_2\text{H}_5\text{O}$) groups. Animal experiments have shown that perparine has an action like that of papaverine, but two or three times more intense, whilst the toxic action of the former drug is only about one-third that of the latter. A combination of perparine and novatropine (brom-methyl homatropine) has been found particularly efficacious, and the mixture has been named surparine. Clinical studies suggest that perparine and surparine may prove a valuable substitute for morphine in the treatment of

a number of conditions in which pain is produced by spasm of plain muscle. Some of the disorders that have been treated with success are biliary colic, cholecystitis, vesical spasm, renal calculus, asthma, and dysmenorrhoea.

ROLL OF BIO-PHYSICAL ASSISTANTS

The question of the establishment of a comprehensive register, under the control of an independent body, of those engaged in services ancillary to the work of the medical profession, has been under consideration for some time past by the Science Committee and the Council of the British Medical Association. A scheme for such a register has now been prepared by representatives of the bodies concerned—namely, the Society of Apothecaries, the Chartered Society of Massage and Medical Gymnastics, the Society of Radiographers, and the British Medical Association—and received the approval of the Council on April 4th. It is proposed that the register shall be known as the *National Register of Medical Auxiliary Services*, and brief particulars appeared a fortnight ago in the Annual Report of Council.¹ Admission to the roll will be confined to persons possessing qualifications granted by the qualifying bodies represented on the Board, subject to certain conditions, including one that they will not treat any patient except under the direction and control of a registered medical practitioner. Pending the establishment of a comprehensive roll of medical auxiliaries, we republish this week as a Special Supplement the complete list of names on the *Register of Bio-Physical Assistants*, revised to March 31st. The entries in Part I are arranged in alphabetical order, with postal addresses; in Part II the names are regrouped geographically. Since the British Medical Association was primarily responsible for the setting up of this register, we hope that members will preserve the *Supplement* and send their patients who require treatment by light and electricity to technicians holding the diploma of the Society of Apothecaries.

G.M.C. ELECTION

The result of the voting in the recent election of a direct representative for England, in the place of the late Dr. Christine Mary Murrell, was as follows: Dr. H. G. Dain, 11,091; Dr. E. A. Gregg, 3,194. Dr. Dain has accordingly been elected a member of the General Council of Medical Education and Registration of the United Kingdom, representing the registered medical practitioners resident in England, for a period of five years from April 27th, 1934. Dr. Dain's letter asking for the support of medical practitioners in his election was printed in the *Supplement* of April 7th, along with a list of those officers of the British Medical Association, of Local Medical and Panel Committees, and others, who signified their intention to forward his candidature.

We regret to announce the death, at the age of 84, of Professor William Henry Welch. One of the pioneers in bacteriology, Professor Welch was appointed pathologist and the first dean of the Medical School at the Johns Hopkins Hospital when it was opened in 1889, and has been president of the Board of Scientific Directors of the Rockefeller Institute for Medical Research.

"CINERADIOGRAPHY"

DEMONSTRATION AT ROYAL SOCIETY OF MEDICINE

A special meeting of Fellows of the Royal Society of Medicine was held on May 1st for two demonstrations of x-ray cinematography, one by Dr. Russell J. Reynolds of Charing Cross Hospital, and the other by Dr. Robert Janker of Bonn. There was a large attendance. Mr. WARREN LOW, the president of the Society, said that Dr. Russell Reynolds, as long ago as 1925, had shown motion pictures of the joints and the thorax; Dr. Janker also had been working on the subject since 1926.

DR. REYNOLDS'S FILMS

Dr. RUSSELL REYNOLDS said that his first experiments were made in 1921, when he was impressed with the extreme value of cinematography in studying movements of joints and functions of organs. Rapid serial skiagrams could be obtained by the direct or indirect method. With the former the series was taken on a band of film by the action of x rays passing through the subject, as in ordinary radiography, but that was costly on account of the size of film and amount of apparatus. With the indirect method the actual photograph was taken of the shadow on the fluorescent screen. An ordinary cinematograph camera, fitted with certain adaptations, was used. The three essentials were: a sufficiently brilliant screen image; the cutting off of the direct x-ray beam so that only ordinary light reached the film; the protection of the subject from excessive radiation. Satisfactory pictures of the movements of the abdominal viscera had only lately been made possible by improved x-ray tubes, photographic lenses, and cinematograph film. The camera and film were protected from radiation by a lead shield; the lens itself sufficiently protected from direct rays the portion of film being exposed. By synchronization of the work of the x-ray tube with the movements of the shutter it was ensured that radiation from the tube was only emitted during the successive openings of the shutter, and in that way the subject was spared undue exposure. Sixteen seconds' exposure to one area had been given, and repeated within a few days, without ill effect on the patient. For making and breaking the primary current a series of contacts around a rotating disk made of insulating material was employed. The source of radiation was a 20 kilowatt "metallix" tube, and the power plant a one-valve unit. A Zeiss lens, aperture 0.85, fitted with a micrometer screw collar for adjusting the focus, was adapted to the standard cinematograph camera, and a special screen and specially coated films had been employed. The film was sub-standard, 16 mm., thus ensuring a process simple enough for routine practice in hospitals, and an apparatus of not undue bulk, and capable of being operated by one person. A small length of film could be made into a band and projected continuously, so that movements could be studied for an indefinite period instead of for the few moments of the ordinary screen examination. The actual exposure generally occupied only a few seconds, and the resulting negative was repeated over and over again, either as a continuous band or a long spool. The material was non-inflammable acetate film, and so could be projected without special protection against fire. The field for research by this method was large and varied. It should prove of use in investigating conditions of the lungs and pleurae; the movements in the alimentary tract with the opaque medium could be followed; in orthopaedic lesions the movements of the joints could be closely studied. In cardiology the present use of x rays was chiefly to check physical signs, and radiology had contributed little to a knowledge of the function of the heart. The cinematograph method was likely to add greatly to such knowledge. A method of cardio-analysis in the shape of a slow-motion film correlated with graphic records of the heart's action had been worked out. The permanent records of these and the other subjects had the r value for diagnosis, for teaching, for comparison with previous records to watch the effect of treatment or the progress of a pathological condition, and for trans-

mission at home or abroad for examination by other specialists.

Dr. Russell Reynolds next exhibited two reels, beginning with x-ray cinematograph pictures of the movements of the hand and the elbow, shoulder, and knee-joint, illustrating both normal and pathological conditions, and he then passed on to a study of the stages of deglutition with the opaque meal, the mechanism of swallowing liquid and solid medium, and the movement of food in the oesophagus, where the food appears to build up at the lower end, and then suddenly to pass into the stomach. The pathological stomach, including one with an ulcer crater on the lesser curvature, was excellently shown. A view of the thorax had an almost stereoscopic effect, and the movement of the normal heart, including its accelerated action after special exertion, was studied, together with two views of pathological conditions, illustrating the irregularity of movement in auricular fibrillation and the effect of pericardial adhesions.

DR. JANKER'S FILMS
